I*

This paper is based on observations made on 184 atients suffering from pneumonia and treated at the ammersmith Hospital (London County Council) etween February, 1932, and April, 1933. They were ivestigated from the clinical, radiological, and boratory aspects. In addition, the records of the iddlesex and Royal Free Hospitals over a period of n years have been examined.

The Mortality of Pneumonia

In 1907 the first meeting of the newly formed ction of medicine of the Royal Society of Medicine[1] as devoted to a discussion on pneumonia. Statistics ere obtained from ten of the leading London hospitals r the years 1897–1906 inclusive, and the 6735 case-cords available gave a mortality of 23 per cent. owan and Harrington[2] analysed the records of the lasgow Royal Infirmary over a similar period (1920–9) and found a mortality of 21·5 per cent. in 1415 ases; it fluctuated from year to year between 16·2 nd 27·3 per cent. Armstrong[3] studied 706 cases dmitted to St. Bartholomew's Hospital during the ears 1925–29 and reported a mortality of 16·6 per ent. A more recent survey from Birmingham by oules[4] of 496 cases of "primary pneumonia" howed that 25·6 per cent. were fatal.

Finally the records of the Middlesex and the oyal Free Hospitals have been analysed for the eriod 1922–31, and if children below ten years of ge are excluded, the mortality is 19 per cent. for 59 cases.

In the United States pneumonia seems to be more atal, although Cecil of New York maintains that he death-rate has been "distinctly lower since 1919." n Cecil's Bellevue Hospital series[5] of 1849 cases there as a mortality of 33·9 per cent., and other American ecords support the impression that the disease is elatively severe in that country.

All statistics show clearly that mortality increases ith age. This was evident in the Royal Society f Medicine series of 1897–1906 and is apparent also in series from the Middlesex and Royal Free Hospitals, 922–31 (Table I.). In both groups there is a decided ncrease in mortality with age, but the series of 1922–31 show an appreciable reduction especially in the age group 20–40.

The 1922–31 series yield further information. If none but the cases which fall between ten and fifty years are included, a total of 542 is obtained, and of these 70 died—a percentage of only 13. With still further selection, limiting the survey to those between ten and forty (a total of 418 cases, with 36 deaths) the mortality is 8·6 per cent. In Joules's series, which were cases largely drawn from the "very poor," the mortality in the 10–40 age-group was 12·5 per cent.

TABLE I.—*Percentage Death-rate in relation to Age*

Period.	Cases with mortality per cent.	Age-group.					
		10–20	20–30	30–40	40–50	50–60	60
1897–1905	682 (24·3) (Roy. Soc. Med.)	5·2	14·2	34·3	39·3	46·6	68·6
1922–1931	859 (19) (Middlesex and Royal Free)	6·0	6·0	18·0	27·[illegible]	42·0	63·0

In a modern investigation the mortality figures must be correlated not only with age but also with type. Cecil, Baldwin, and Larsen[6] showed that Type I. pneumonia was most common under forty years of age. Of 1092 cases of pneumonia under forty, no less than 426 (40 per cent.) were due to Type I.; over that age out of 795 cases only 202 (25 per cent.) were due to this type. There is therefore a high incidence of Type I. infection under forty, and this is the period of better prognosis. Blake[7] made a similar study and found a still higher proportion in his cases: under thirty-nine years 80 per cent. were due to Type I., whilst over forty the incidence fell to 20 per cent.

If we are to regard Type I. pneumococcal pneumonia as being the commonest form to attack those under forty years of age, then the period of life most favourable for spontaneous recovery corresponds to the incidence of the type most amenable to serum therapy. It may therefore be difficult to determine in a serum-treated case what factor saves life. In the series here described we therefore selected the more serious cases for specific treatment (instead of alternat rs cases) as affording a more stringent test of the valup. of serum.

Type I. Pneumococcal Pneumonia

*Parts II. and III. will appear in forthcoming issues of THE LANCET.

Ameri .. .nd British workers, that Type I. accounts for so.ne 30 per cent. of all cases of pneumonia.

During the period February, 1932, to April, 1933, we had 184 cases of lobar pneumonia under observation, and of these, 137 showed a type incidence as follows:—

Type I.	55 cases	(40·0 per cent.)
Type II.	13 ,,	(9·5 ,,)
Type III.	20 ,,	(15·0 ,,)
Group IV.	49 ,,	(36·0 ,,)

In addition there were—

Two types	12 cases.
Streptococcal	4 ,,
Untyped	31 ,,

Incidence in relation to age.—Of 1380 cases of Type I. pneumonia studied by Cecil,[8] 806 (59 per cent.) were in persons between ten and forty years of age—broadly speaking, in young adults. Of the 194 Type I. cases recorded by Blake[7] 80 per cent. were in persons below forty. In the Medical Research Council's combined statistics[14] of 485 Type I. infections, 364 of the patients were between twenty and forty, an incidence of over 70 per cent., while only 121 were between forty and sixty. Apparently it is uncommon to find Type I. pneumococcus in the pneumonia of the very young, and Cecil[8] regards it as an extremely rare infection under the age of three. Our group of 55 Type I. cases agreed in showing a preponderance of patients under forty:—

Years.	Cases.
10–19	11
20–29	16
30–39	11
40–49	9
50–59	5
60	0

There is therefore good evidence to regard Type I. pneumonia as an infection which predominantly affects the young adult. This in its turn carries with it a good prognosis.

MORTALITY

It is necessary to have some estimate of the mortality of this form of pneumonia in the absence of special treatment, and if possible to know the ›xpected mortality in relation to age. Since it is form predominantly attacking the young and healthy, would not be difficult to compile a large series with very low mortality, and this must be borne in mind en assessing the value of any specific remedy. as been clearly shown that Type I. pneumonia is ore dangerous disease in America than it is in and, but this conclusion has to be qualified by ıct that our compiled statistics are less extensive. ıath-rate in America *is given as* 25–30 *per cent.*, en there it varies according to the class from the *different institutions* draw their cases. ves a mortality of 28·2 per cent. at Bellevue Lord[15] 24·7 per cent., Blake[7] 23·2 per cent., 29 per cent., and Sutliff and Finland[17] ;ent.

;aldwin, and Larsen[6] found the mortality of 'ection in relation to age to be:—

8·4 % deaths.	40–50.. ..	21·0 % deaths.
16·0 % ,,	50–60.. ..	26·6 % ,,
17·8 % ,,	60	31·2 % ,,

y school[18] found in a series of 1118 e death-rate for Type I. pneumonia was ent. Langley,[19] however, in Manchester aths in 99 cases—a mortality of 20 per ıbined total of the Medical Research (301 untreated cases) showed a er cent.

·ies of 55 cases of Type I. pneumonia es deemed serious enough to have serum treatment, and the remaining 36 all recov without the aid of any specific therapy. Since we know that the mortality from all types of pneumonia is lower in this country than in America, we deduce that the *mortality here from Type I.* pneumonia cannot on the whole be much greater than 10–15 per cent.

CLINICAL PICTURE OF UNTREATED TYPE I. PNEUMONIA

As just stated, there were 36 *patients who had no* treatment and they all recovered. The average age for the group was *thirty*: 23 *terminated by crisis* and 14 of these showed a normal temperature on or before the seventh day, while 21 were afebrile before or on the ninth day. Like other observers, we have found a sustained temperature with a swing of about 2° in the majority; the range was usually from 102°–104°. The younger the patient the higher the temperature. The infection, if judged by the respiratory rate, was moderately severe; for in 31 the respiratory rate was above 30 and in 16 was 40 or more. Thirty of the cases showed a pulse-rate above 120. The pulse-rate rapidly returned to normal after the crisis. In assessing any form of treatment it is imperative to know the stage of the pneumonia *at which the case is first seen. In this* group it was possible to ascertain the exact date of onset in 28 cases—the pneumonic onset being sudden and ushered in by such dramatic symptoms as rigor, vomiting, or sudden pain. In eight of the cases there were some *atypical features* and the exact day of onset somewhat doubtful.

Only 4 of this group gave a past history of chronic chest trouble; their course was far more distressing than that of others with a clear history.

Typical signs of consolidation were obtained on admission in 24 cases, atypical signs in 9, and no signs at all in 3, though these had become definite 24 hours after admission. Extension into another lobe was observed in 6 of the more serious cases. A feature common to almost all this group was the rapidity with which the signs of *consolidation* disappeared; for in 27 of the 36 cases no physical signs were elicited *after* the twenty-first day. In only 2 was there a delayed resolution. Empyema developed in 3 of the cases; this was treated by aspiration in 2 and by rib resection in the other.

Type I. pneumonia has been regarded as the pneumonia of the "healthy" young adult. It is the form which shows all the classical features of "acute lobar" pneumonia—the high sustained fever (Chart 1), the clear-cut onset, and, in a large majority, the sudden cessation of distress with a sharp crisis. Our group of 36 is in keeping in several respects, the youth of the patients (average age thirty), the infrequent past chest history, the comparatively common "early" crisis (Chart 2), and the absence of *any profound or progressive toxæmia in the majority.* (In an older person the response is less typical.) Favourable and unfavourable features of this type may be classed as:—

Favourable.—(1) High sustained fever. (2) Early crisis. (3) Rapid fall in pulse-rate with cessation of fever. (4) A good initial leucocytosis (20,000–30,000) and a rapid fall in white cells associated with the crisis. (5) No history of chest trouble.

Unfavourable.—(1) An irregular fever. (2) Cyanosis and profound toxæmia. (3) A persistent tachycardia. (4) A persistent high white cell count, or an initial or persistent low white cell count. (5) A persistent bacteræmia. (6) Preceding chronic chest history or existing hypertension.

Seeing that Type I. pneumonia is the form in which serum therapy has been proved useful, it is well to bear in mind the probable benign course in a large proportion of the cases, the not infrequent early crisis and the youth of the average patient.

LABORATORY FINDINGS IN UNTREATED TYPE I. PNEUMONIA

Leucocyte count.—The average leucocyte count, taken at the height of the fever in our untreated Type I. cases, has been 22,000. The general trend has been for the count to fall to 12,000 within three days of the crisis and to 10,000 within the week. In two cases of empyema the same subsidence occurred after the crisis, but with the establishment of the empyema the rise was only to 18,000 and 10,000 respectively.

Blood culture.—In 22 untreated cases blood cultures taken on the day of admission were all negative. Owing to the favourable course of the disease the examinations were not repeated.

Agglutinins.—In our series of untreated Type I. pneumonias we have been impressed with the ease with which agglutinins are developed in the blood and their transitory nature in uncomplicated cases. The most constant finding in straightforward Type I. infections has been for agglutinins to be detectable not just before or at the crisis but about two or three days afterwards; usually they have disappeared after a fortnight. This phenomenon was observed in 14 cases out of 22. On the other hand, cases which developed complications, such as empyema, extension of consolidation, otitis media, or delay in resolution, have almost all shown a persistence of agglutinins beyond the time stated above. With the onset of a complication the agglutinins sometimes disappear, to reappear when the complication has subsided.

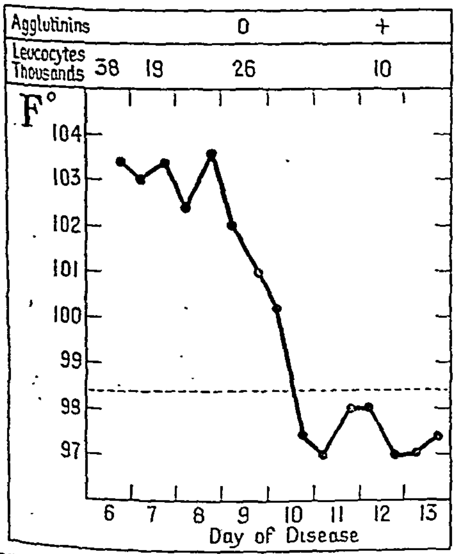

CHART 1.—Type I. pneumonia in a male aged 30. Rapid fall in white cells from 38,000 to 10,000 in seven days. Rapid resolution.

We deduce therefore that agglutinins are substances associated with the process of resolution; their presence, though favourable, is no index of true immunity; rather do they show that the process of resolution is going on. Persistence of agglutinins does not indicate immunity to extension of the disease, to exacerbations, or to complications; it suggests that the process of resolution is not yet over and that the patient is accordingly liable to further trouble. With the disappearance of agglutinins it may be assumed that resolution is complete and the infective process overcome.

Type I. Pneumonia Treated with Felton's Serum

American workers have assessed the value of serum through the investigation of large series and have demonstrated a diminution in mortality in Type I. pneumococcal infections. We, on the other hand, have been forced to adopt a method based on close personal observation of individual cases. From this point of view our series of 19 is divisible into two classes.

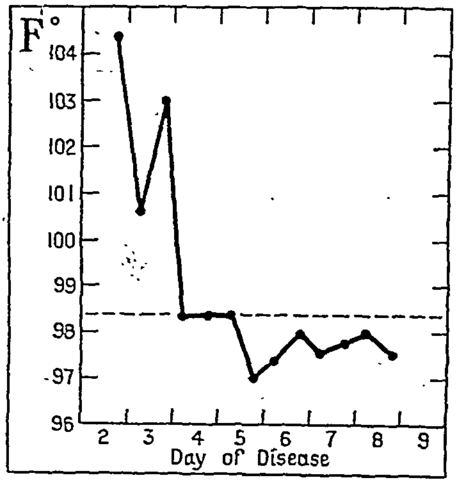

CHART 2.—Type I. pneumonia in a male aged 28. Crisis on fourth day.

(i) Cases in which serum was administered within the first four days of disease—i.e., those falling within the theoretical optimum period for benefit.

(ii) Cases in which serum was administered after the fourth day—i.e., those in which the exploitation of any available measure was justified by the gravity of the illness. A positive blood culture on the fifth day or a rapidly rising pulse and respiratory rate were factors which weighed in favour of serum treatment in this group.

We base our impressions of the value of serum therapy on the relief of symptoms, the fall of temperature, the day of crisis, the speed of resolution, and the incidence of complications.

(I) CASES TREATED WITHIN THE FIRST FOUR DAYS

In the first group 16 cases were treated; of these 5 received serum on the second day, 5 on the third, and 6 on the fourth.

SERUM TREATMENT ON SECOND DAY

Table II. shows 5 cases treated on the second day, all of which recovered. Three had a crisis on the third or fourth day, while the remaining two became afebrile on the fifth. There was an undoubted amelioration in respiratory distress, and it was commonly noted that after an initial dose of serum the patient slept quietly for some hours. These patients coughed and expectorated less than those

TABLE II.—*Cases treated on the second day*

E. = exacerbation.

untreated, although frequently they were disturbed for a few minutes after the administration of serum in their efforts to expectorate a frothy and abundant secretion; this temporary distress was rapidly replaced by an attitude of comparative comfort. At first it was a surprise to see a pneumonic patient on the fourth day of the disease sitting up in bed, shaven and reading the morning papers. In their relative well-being they contrasted forcibly with the untreated patients who, still dyspnœic, showed little interest in their surroundings. The pulse and respiratory rate closely followed the temperature, there being an immediate fall in all three. Four out of the five cases showed a pulse of 80 or below 80 on the fourth day of disease.

Of these 5 cases 3 were poor risks, giving a long history of previous respiratory infections; one other was severely toxic with a low blood pressure, an enlarged heart, and bilateral signs of consolidation. In all 5 cases the signs observed in the lungs increased as the fever subsided, and in one case they were massive on the seventh day; but despite massive signs, resolution was complete in 4 out of the 5 cases by the sixteenth day. None of this group developed an empyema.

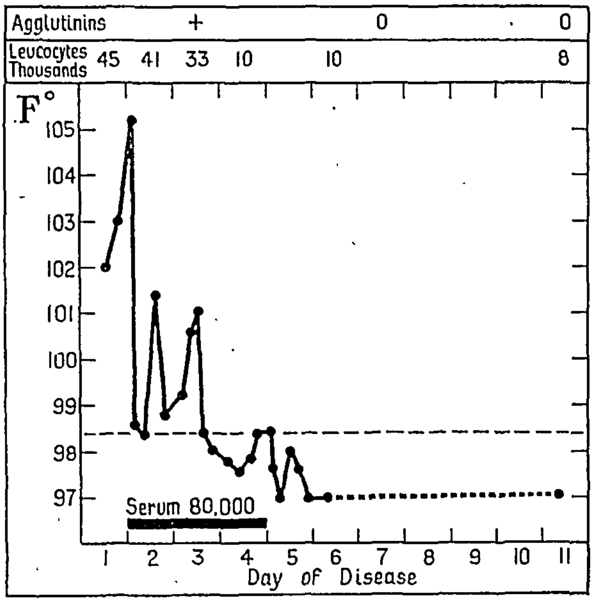

CHART 3.—Type I. pneumonia, serum-treated. Crisis on third day.

Chart 3 shows the effect of serum therapy on one of this group, in whom the blood culture was positive on admission. This patient was a chronic bronchitic and severely ill.

Leucocyte counts.—A noticeable feature in these early serum-treated cases was the speed with which the high initial count returned to normal. After the crisis, the count fell within 24 hours from 33,000 to 10,000, from 25,000 to 10,000, and from 18,000 to 9000. Continuous observations on the serum-treated cases showed that in the period of delayed serum sickness, 7, 8, and 9 days after serum, when joint pains and some fever were present, there was a rise in leucocytes often as high as 17,000–20,000. In a serum-treated case this fact should be borne in mind when using the leucocyte count as evidence for the existence of an empyema.

Blood culture.—Of the 5 cases 1 had a positive blood culture on admission. The course of this case was the most favourable of all our serum cases. There was a crisis within 24 hours of giving serum.

Agglutinins.—Felton's serum contains specific Types I. and II. agglutinins, as well as specific protective substances. In interpreting results it is therefore necessary to consider the agglutinins that have been passively introduced, as well as those that are produced actively by the patient. A dose of 10 c.cm. (20,000 units or more of Felton's serum) introduces a theoretical sufficiency of Type I. agglutinins for detection in the peripheral blood shortly afterwards; Type II., on the other hand, requires the injection of 20 c.cm. or more.

We have been unable to observe any rapid "absorption" or "neutralisation" of homologous agglutinin antibody when such is injected in the form of Felton's serum; the homologous agglutinin has been easily detectable within a few hours of giving the serum and, as far as can be judged, at least as long as the heterologous agglutinin. Nor have we found any evidence that the agglutinin content of the patient's serum is any guide as to the sufficiency of the serum administered. Sabin[20] and others have claimed that not only does the presence of homologous agglutinin indicate that sufficient serum has been given, but also that the disappearance of homologous agglutinin during serum therapy (as contrasted with the persistence of the heterologous agglutinin) is sufficient evidence for making a type-specific diagnosis as well as for indicating that more serum is required. With these views we do not agree.

SERUM TREATMENT ON THE THIRD DAY

The 5 cases treated on the third day of the disease are summarised in Table III.; 4 survived and 1 died. An early crisis was obtained in 2 (on the fourth day); one of these (J) died later of meningitis. Another was afebrile on the fifth day, another on the seventh, whilst the last (I) was not afebrile until the ninth day, and then only for 24 hours, after which his temperature again rose with serum sickness. While all five experienced symptomatic improvement, the response was not so definite as in the cases treated on the second day, although in three of the cases the pulse-rate was 80 or under on the fifth day.

TABLE III.—*Serum given on third day*

Case.	Age.	Crisis.	Resolution.	Complications.	Units dosage.	Serum sickness.
F ..	28	4th.	27th.	Nil.	70,000	+
G ..	20	5th.	37th.	Sore-throat.	130,000	0
H ..	45	7th.	55th.	Extension of consolidation.	120,000	+
I ..	27	9th.	22nd.	Nil.	120,000	+
J ..	28	4th.	Nil.	Meningitis (death).	140,000 50,000	0

One patient, a poor risk, gave a history of two previous attacks of pneumonia; he had an emphysematous chest, was ill-nourished and delirious, and had a positive blood culture, as well as a low blood pressure (90/60). In his case there was no dramatic fall in temperature following treatment, but the amelioration of symptoms, the rapid recovery, and the immediate fall in white cells turned a gloomy into a bright prognosis, and we are bound to attribute this change to the administration of serum.

Leucocyte counts.—As in cases treated on the second day, there was, where a favourable result was obtained, a quick fall in the leucocyte count. Though the immediate fall was not as rapid as in the second-day series, there was nevertheless a speeding-up of the fall as compared with the untreated cases, the average count eight days after the crisis being 7000. Observations on three cases at the most intense phase of delayed serum sickness reaction showed an average count of 22,000.

Blood culture.—In this group of five cases there was one with a positive blood culture.

Agglutinins.—As in cases treated earlier, agglutinins were detectable within a few hours of the introduction of Felton's serum. These passive agglutinins, in favourable cases, merged into those actively produced by the patient, and were present throughout the whole period of resolution.

SERUM TREATMENT ON THE FOURTH DAY

Of 6 in this category, 2 experienced a crisis on the fifth day, 2 were febrile until the ninth day, and in the remaining 2 fever persisted and merged into the fever of complications (Table IV.).

Definitely favourable responses were obtained only in young people—20 and 24 years of age—in whom an early crisis might be expected. Of the 4 older subjects, all were obviously improved symptomatically as the result of serum. There was, however, no immediate effect on the temperature, and in 2 the fever of the pneumonic process merge into that caused by an empyema. All 4, from the clinica [illegible], appeared in urgent need of medical help, and we [illegible]der that serum contributed to their recovery.

From the 6 cases we concluded that 2 reacted specifically to treatment with serum, while the other 4, although they showed no immediate effect, appeared to benefit. Thus there was less respiratory distress, less coughing, and little, if any, expectoration. The incidence of empyema was noticeably high, and it may well be that the lessening of respiratory embarrassment encourages the retention of inflammatory products within the lung and so facilitates formation of an empyema.

TABLE IV.—*Serum given on fourth day*

Case.	Age.	Crisis.	Resolution.	Complications.	Units dosage.	Serum sickness.
K ..	20	5th.	10th.	Nil.	60,000	0
L ..	24	5th.	12th.	Nil.	60,000	0
M ..	35	—	—	Empyema.	90,000	0
N ..	41	9th.	—	Empyema.	130,000	0
O ..	45	—	29th.	Hip abscess.	120,000	+
P ..	51	9th.	21st.	Nil.	60,000	0

Leucocyte count.—In the two favourable cases the leucocyte counts showed the usual rapid fall soon after the crisis. In the other cases, the original disease was so merged in the subsequent purulent complications that no fall in leucocytes was observable as a result of the serum therapy.

Blood culture.—One patient in this group had a positive blood culture on admission. He later developed an empyema. The clinical course was no more unfavourable than other cases.

Agglutinins.—In principle the same results were observed as previously described. One patient had no agglutinins at any phase, but the other 5 all had them in the peripheral blood a few hours after giving serum; they were easily detectable during the period of resolution, and, in cases with complications, so long as these were present. It is interesting to note that in one of the empyema cases the agglutinins disappeared at the end of what we had come to regard as the normal period of resolution, but reappeared with the onset of empyema. It is clear that agglutinins are no indication that a given case will be free from complications. Recovery from a complication appears to excite agglutinin formation in the same way as recovery from a straightforward pneumonia.

(II) CASES TREATED LATE IN THE DISEASE

Of three patients in this group (Table V.) one died. All three were given serum as a forlorn hope on the sixth day, because their condition was regarded as desperate. Yet even in this series two showed such rapid symptomatic improvement that we could only attribute the change to serum; one of these had a positive blood culture (sixth day), but the temperature and pulse were normal within 24 hours of giving the serum. The fatal case showed immediate symptomatic improvement, but the patient died about ten days later and two small loculated basal empyemata were found at autopsy.

TABLE V.—*Serum given late in the Illness*

Case.	Age.	Crisis.	Resolution.	Complications.	Units dosage.	Serum sickness.
Q ..	28	8th.	15th.	Nil.	60,000	0
R ..	36	7th.	16th.	Nil.	70,000	0
S ..	48	—	—	Bilateral empyema (died).	120,000	0

DISCUSSION

The cases selected for serum treatment were those which symptoms were severe or the risk poor. Two ended fatally—one from meningitis after an apparent recovery, and the other from a bilateral deep-seated empyema. Both of these had shown an initial response to serum.

In this group of 19 cases, which includes 3 treated on the sixth day, a positive blood culture was found in 4, though in the 2 patients that died the blood was sterile. It speaks favourably for the potency of serum that the 4 showing a positive blood culture recovered, and of these 1 was positive as late as the sixth day.

The effect of the serum on the symptoms was undoubted. In the early case it was immediate and the febrile period was obviously shortened. The patients were made far more comfortable and their respiratory embarrassment was greatly allayed, although the signs of consolidation remained or in some cases actually progressed, even though the crisis had occurred and the patient was afebrile.

American publications have shown the efficacy of serum in reducing the mortality of Type I. pneumonia. To Cecil, whose statistics are still the best and largest, the chief credit is due for this clinical demonstration. Of 103 cases treated within the first three days of illness he lost only 12, a mortality of 11 per cent.[8] Up to date he has treated 239 cases of Type I. with a mortality of 20 per cent., compared with a control mortality of 31 per cent. Cruickshank[13] has collected the compiled statistics of serum-treated Type I. cases in U.S.A. and this country as follows:—

	Cases.	Deaths.	Mortality.
Treated	547	94	17·3 per cent.
Untreated ..	477	148	31·0 ,,

The Medical Research Council report[14] gives the following figures from the four British centres:—

	Cases.	Deaths.	Mortality.
Treated	184	18	9·7 per cent.
Controls	301	45	14·7 ,,

It is very necessary to obtain a large series of treated cases to establish the value of serum therapy. This has been done in America, but the figures are not applicable to this country since, as we have said, there is reason to believe that Type I. pneumococcal pneumonia is less fatal here. Theoretically, serum therapy should show not only a reduction in mortality but also a shortening of illness and alleviation of distressing symptoms.

Our cases showed definite symptomatic benefit, and although this was more obvious where the serum was given within the first three days, we concluded that some effect was obtained when it was given later. If antipneumococcal serum is specific we think it should not be withheld from patients desperately ill in the sixth or seventh days. Although at this late stage its effects can only be judged by clinical impression, such judgment is not without value. There must be many cases where the exhibition of serum even late in the disease might prolong life for an extra day and thus allow a crisis to be established. From our limited experience we would regard any case of Type I. pneumonia as being in need of serum if the condition was severe and the prognosis uncertain. Moreover, since serum may "abort" the disease when given early, its use should always be considered in cases seen during the first three days; if it shortens the febrile period it will make extension or relapse less likely.

SERUM REACTIONS

Some immediate reaction was observed in all the 19 cases to which serum was administered. The pulse became faster, the patient perspired profusely, and general distress was greater. Only once did this immediate reaction reach alarming proportions, this in a man of 45. A delayed or thermic reaction occurring within a few hours has been mentioned by Leys[11] and one of his patients died of "hyperpyrexia"; but none of our cases showed this reaction.

Serum sickness developed in 6 cases, between the ninth and sixteenth days. Usually such a reaction is shown by joint pains, joint effusions, and a rise in temperature; occasionally there is urticaria. We were impressed by the severity and duration of this disturbance, for in many of the patients it caused manifest discomfort for three or more days. The temperature rose to 100° or more. The white cells increased to 15,000–20,000, and the patient complained of severe pains, which often resulted in loss of sleep and so delayed convalescence. There was little evidence of joint effusion in our cases; indeed, little could be found wrong in the joints except that movement was acutely painful. It was observed that the white cell count often rose before the onset of symptoms, while the fever usually returned pari passu with joint pains.

THE RESULTS OF FIFTY CASES TREATED BY PSYCHOTHERAPY

BY W. LINDESAY NEUSTATTER, B.Sc., M.B., M.R.C.P. Lond.

PART-TIME MEDICAL OFFICER AT THE MAUDSLEY HOSPITAL, AND PHYSICIAN TO THE BRITISH HOSPITAL FOR FUNCTIONAL, MENTAL, AND NERVOUS DISORDERS, LONDON

THIS paper summarises results obtained in the treatment of fifty patients at the Maudsley Hospital during 1933. Their ages ranged from 17 to 48, and twelve of them were women; they were referred to me from the out-patient department by other members of the staff,* and were seen for half an hour at a time. The maximum number of interviews was three per week; the minimum cannot be fixed, but some of the patients were seen only once every two or three weeks.

Unfortunately there is no objective standard by which a "cure" can be measured. Ability to return to work is one criterion accepted by the Maudsley Hospital for the use of the term "recovered," but as many of my patients remained at work during their treatment, it cannot be applied here. The cases have therefore been classed as Improved and Unimproved,† the former group being subdivided as follows:

Slight.—This merely implies that the patient felt somewhat more comfortable than he did to begin with. His symptoms were either less intense, or attacks were somewhat less frequent.

Moderate.—The patient's symptoms showed a satisfactory diminution in intensity or frequency, but nevertheless had not disappeared.

Considerable.—Complete or almost complete disappearance of symptoms.

The terms are not satisfactory, depending as they do on a mixture of the physician's observations and the patient's own assessment of his feelings. In functional disorders, however, the patient's comfort and ability to carry on is so far linked with subjective conditions that his feelings may be allowed relatively greater weight.

The four types of treatment used may be described as follows:—

Medicine and Reassurance.—The nature of the symptoms was explained to the patient. He was told that other people had similar ones, that there was no danger (especially of insanity), and that he would recover. The medicine given depended on the conditions present; usually pot. brom. was employed, though occasionally a placebo such as mist. gent. c. sod. was prescribed. If there was any organic disorder this was treated appropriately, but not during analytic treatment. It was found inadvisable for the psychologist to act as the general medical attendant, and the patient's own doctor was enlisted to deal with such problems.

Suggestion.—Here the patient was made to lie down, and a slightly hypnoidal state was induced. Suggestions of recovery were made, both general and specific for the symptoms.

Psychological Talks.—The patient was seen once or twice a week. His history was gone into, and symptoms reviewed and explained in the light of their apparent ætiology.

Analytic.‡—The patient was made to lie down. Free association, with or without the use of dream material, was employed. The transference was analysed. The patient was never seen less than twice a week, and usually three times. Treatment extended over some months, though never above nine and rarely longer than six. Sessions lasted half an hour.

RESULTS

Of the 50 patients 32 improved, 16 failed to so, and 2 got worse.

Anxiety States.—The results in this group are s out in Table I.

The severe case which improved considerably was one of long standing, previously treated elsewhere, without avail, by medicine and reassurance. Of the two moderately severe cases with considerable improvement one was a woman of 35 with an acute anxiety state, who had 43 analytic sessions. In her case the anxiety gave way to a good deal of sexual desire, which had been absent previously. As she was a person who stood a reasonable chance of getting married, this was not unsatisfactory, though it raises the question whether such a substitution would be beneficial in all cases. The other patient was a man of 43, who improved after 11 psychological talks.

---

* As the whole question of psychotherapy is a controversial , I would like to make it clear that once a patient was handed to me I was allowed to use my own discretion regarding the of treatment adopted. These methods, therefore, were necessarily endorsed by other members of the staff.

† The results were those obtained at the time of discharge. As no "follow-up" was done, there are no reports from relat or friends to confirm or refute them.

‡ The term "analytic" is used as opposed to psycho-analysis in the Freudian sense. The method employed differed in so as the sessions were less frequent and shorter, and the treatm did not last nearly so long. Although a transference was es lished and analysed, where necessary advice and occas reassurance was given, and a certain amount of persuasion I think the physician is in a position to distinguish be demands for reassurance and advice which are arising fro analytic situation, and where these demands are really a priate and determined by a reality situation. The m corresponds largely to that of Stekel of Vienna.

TABLE I.—*Anxiety States*

	Cases treated.	Improved: Considerably.	Improved: Moderately.	Improved: Slight.	Unimproved.
Moderate	17	2	7	5	3
Severe	7	1	—	1	5
Totals	24	3	7	6	8

Of the 8 cases which were unimproved, 5 were chronic and 3 subacute. Six of them, moreover, discharged themselves without warning from the second to the tenth session. Five patients (4 of them being among the self-dischargees) had been treated medicinally before.

TABLE II.—*Depressive Cases*

	Cases treated.	Improved: Considerably.	Improved: Moderately.	Improved: Slight.	Unimproved.
Moderate	8	2	5	—	1
Severe	3	—	—	2	1
Totals	11	2	5	2	2

Depressive Cases.—These are summarised in Table II. One patient who improved considerably was in a recurrent depression at the third spell; he was seen three times. Of the unimproved, one was a case of depression in the puerperium, which came to me at the beginning of a relapse, and the other a man who was worried and dissatisfied with his work, and who showed paranoid features.

One depressive who improved was a man who suffered from listlessness and lassitude. He worked 13 hours a day and only had one Sunday off in three as spare time. This lassitude was at first attributed to overwork, but after a month the symptoms improved with no change in the external conditions. This is of interest, since overwork is often stated to be a cause of neurotic conditions, yet here was a grossly overworked man who improved.

Obsessionals.—Of 3 patients treated, 1 improved and the other 2 were unimproved. The case which improved was a severe one and the improvement shown was considerable. The patient was a man of 60 who had been overworked in the office and had two previous attacks. He was treated with a holiday, bromide and reassurance, and improvement took place gradually over six months.

Both the unimproved cases were moderately severe. One was subacute, and the patient had to leave London after six sessions because of his employment.

The other was acute and was treated analytically at 21 sessions; the patient then discharged himself but has since returned. We had been discussing his hostile attitude towards his father, and he suddenly felt an impulse to leave; "treatment was useless." On resuming treatment we soon returned to the subject of his attitude towards his father, and he said that it again had aroused a strong impulse not to come up. He was again under treatment for a month, twice weekly, but failed to return to me after a holiday.

Hysteria.—Improved, 4; unimproved, 2. Of the former, one was a severe case of "faints" which improved considerably; and of three moderately severe cases one improved considerably and the others moderately. The patient who improved considerably had fits resembling tetany; he was seen 7 times, and reassured.

One of the moderate cases was analysed at 36 sessions, thrice weekly. She was a woman of 45 who had hysterical feelings of faintness, which were never witnessed, and which improved but did not disappear, according to the patient's account. She was an interesting case from the point of view of the importance of external and internal factors. An educated woman who had lost all her money and could trace no relations, she had supported herself for many years. When first seen she was unemployed and was living on 17*s.* a week. After a month she again obtained employment. There was no improvement in her symptoms after she returned to work. Although she was very emotional and unable to grapple with problems of a subjective and especially a "moral" nature, she never gave way under the strain of her very difficult circumstances.

One of the cases that failed to get better was a hysterical amnesia in a woman of 24 which did not improve after 48 sessions of psychological talks; the other was a case of sleep-walking and dermatitis artefacta, in which the patient attended nine times but "failed to see why she should be treated at all."

Sexual Difficulties.—A number of cases of sexual disorders were seen during the year, but apart from one patient with frigidity, none of them could attend over any length of time and no attempt was made to alter the sexual disability. In the time available it was possible, however, to do something to relieve their anxiety or depression—often by adjusting their attitude towards their own difficulties.

Four cases of homosexuality were seen in this group. One patient, a married man, had committed an offence which he was very disturbed about. A second, a strapping man, working to support his mother, considered himself "a moral degenerate," and was not unnaturally depressed in consequence. A third was very unhappy about his condition, not from the social point of view but because of his inability to lead a satisfactory sexual life along the lines he desired, and had on three occasions attempted suicide. He had never had heterosexual inclinations up to the age of 26, but then had intercourse with a woman and was potent, though deriving very little satisfaction from the act. He and the married homosexual are interesting as examples of "bisexual" men.

As these cases were never treated for their sexual difficulties they cannot be included numerically, and have been mentioned from the point of view of interest only.

The single case treated was one of frigidity in a woman of 30, who had been previously treated by reassurance and advice, but to no avail. She improved after 76 sessions of analysis, at the end of which time she was also given advice regarding technique. This advice had been given previously, but had never been accepted, so it appears reasonable to argue that the analysis had brought about the change that made it possible for her to arrange her sexual life in a way that would bring her pleasure. She also became a much quieter and less agitated person.

Schizophrenics.—Four were treated, with no improvement. One was a man of 25 with obsessional features. He suddenly left after ten sessions of an analysis which was being tried and got married (of which he had said nothing). The others were under 20. Two of them discharged themselves, and the fourth, who had gonorrhœa, and who insisted that he should be at liberty to have sexual intercourse without any measures being taken to prevent infecting his partner, was referred back to the venereal diseases clinic as being unresponsive to psychotherapy.

Behaviour Problems.—There was one case only, that of a girl of 17 in service, who had temper tantrums. They were brought about by a family situation and the girl's mismanagement by her mother. The difficulties improved considerably with half a dozen talks.

DISCUSSION

One of the obvious difficulties of psychotherapy is the expenditure of so much time on single cases. This particularly applies when the patient has small means, or at a clinic where a comparatively large number of cases have to be treated. It becomes important, therefore, to determine the most satisfactory method of treatment, and to decide how far a given case will prove responsive. In a hospital clinic it is especially undesirable to spend much time over a case which will not respond to treatment at the expense of one which will. Similarly, unless there is very great advantage to be gained by a longer method (such as an analysis) rather than a shorter, the latter should of course be chosen.

In a paper like this, dealing with only 50 cases, it is impossible to go into detail about the kind of treatment that will prove most satisfactory in particular cases. Moreover, as the method adopted in each case depended only on my own judgment of what was required, the issue is correspondingly prejudged and the findings invalidated. However, it may be worth while to set out the results according to the different methods of treatment used (Table III.).

TABLE III.—*Methods and Results*

Method.	Cases treated.	Improved.	Av. att.*	Unimproved.	Av. att.*
Analytic	10	7	51	3	11
Psy. talks	23	12	14	11	6
Reass. and med.	15	11	7	4	4
Suggestion	2	2	12	0	0

* Av. att.=Average attendance in half-hour sessions.

The comparatively poor results of the psychological talks are to be explained as follows. These are the results of clinical work and not an experimental investigation; I had to decide what method to use, and I was only prepared to embark on an analysis where I felt the trouble would be repaid. Reassurance and medicine therefore were used in the cases that seemed likely to respond most easily, and there was a tendency to keep psychological talks for the cases which clinically appeared to be the hardest to treat.

It will be seen that just over two-thirds of those analysed improved, two-thirds of those having reassurance and medicine, and just under half of those having psychological talks. As I have just said, these were the ones which at the start probably appeared least responsive. Of 10 analysed, 4 had been previously treated unavailingly by reassurance. Out of 16 improving on reassurance and medicine 7 had been previously treated, and 4 out of those treated by psychological talks.

PROGNOSIS

Turning to prognosis, is it possible to discover any factors which will give an idea how far a particular case is suitable for treatment? With this in mind, the following points have been investigated in the cases reported.

1. *Objective factors.*—(*a*) The chronicity and severity of the neurosis. (*b*) The influence of external factors, grouped under business, domestic, and financial worries.

2. *Subjective factors.*—(*a*) The sex life of the patient and whether it is satisfactory. Also the question of conflicts centring around masturbation, since this frequently proved to be a cause of worry. (*b*) Certain rather ill-defined factors discussed below.

While actually working with patients it struck me that there were certain cases which from the beginning appeared more hopeful than others. It was very difficult to be precise about this, but, broadly speaking, the ones who were judged to have a good prognosis were those who were intelligent and coöperative, were really suffering from their symptoms, and had a certain amount of psychological insight, and those whose mental processes and outlook were not too set. The other group were those who "had an axe to grind" with their illness, who were set and self-centred.

Certain of these characteristics have been investigated in the present series to see if anything emerges.

It was found that acute cases were rather more responsive than the others, but the severity of the attack seemed to bear no relation to the response to treatment. This largely agrees with my impression, in dealing with cases, that the actual severity of the symptoms did not necessarily mean poor response to treatment; indeed, it very often seemed to increase the patient's desire for improvement. Table IV.

TABLE IV

	Domestic worries. Per cent.	Business worries. Per cent.	Financial worries. Per cent.
Improved	23	10	10
Unimproved	23	14	14

shows the relation of domestic, financial, and busine worries to improvement, and the figures again agre with the clinical impression that although suc troubles may worry and depress the patient, the do not enter into the structure of the remainin neurosis. The case cited under "hysteria" was a interesting example of this.

Turning to the subjective conditions, Table shows that of the failures over three times as man

TABLE V

	Sex life unsatisfactory. Per cent.	Masturbation. Per cent.	Worry ove masturbatio Per cent.
Improved	14	20	16
Unimproved	50	32	41

had unsatisfactory sex lives—which accords with mos people's clinical findings. Of those who failed t improve nearly three times as many were worrie over masturbation (past or present), or the tempta tion to it—a matter which has to be gone into wit nearly all patients. As will be seen, masturbatio and worry over it do not coincide. This is in accord ance with the views of Stekel[1] who remarks tha "neurosis often commences when masturbatio ceases."

Coming finally to the subjective characteristic above mentioned, we get the following results. Fo clarity the somewhat vague terms have been define as far as possible. They are:

Discontented is where the patient was generally dis gruntled about himself and his affairs, and grumbled good deal.

Distractable means that the patient was prepared t coöperate and listen, as opposed to the type of patien who always tended to return to discussing his particula set of symptoms.

Egotistical: self-centred.

---

[1] Stekel, W.: Onanie und Homosexualität, Berlin, 1921, p. 18.

Somatic is where the physical side of the picture—tachycardia, pains, aches, feelings of pressure—predominated over more purely psychological symptoms.

Discontentedness was present in about half those cases which improved and half those which did not, and distractability in about a third of both. On the other hand obsessional and hypochondriacal features were present in about 10 per cent. of those who improved and twice as often in those who did not. Egotistical and somatic features were present in about one-third of those who improved, and in half those who did not. Depression was present in about two-thirds of both. From this it appears that obsessional features, hypochondriacal, egotistical, and somatic features, tend to make the prognosis worse, as they occurred approximately twice as often in those cases which failed to improve.

Finally, intelligence in relation to improvement was investigated, as was the relationship between improvement and cases discharging themselves. It was found that intelligence played no part, about two-thirds of improved and unimproved being intelligent, and that half the cases who did not improve discharged themselves, averaging nine sessions. None of those who improved discharged themselves.

COMPARISON OF RESULTS

Tabulated reports of the results of psychotherapy are difficult to find, but the results obtained are compared with the annual report of the Institute of Medical Psychology for 1933, and those in Kessel and Hyman's[2] report on the results of psycho-analytic treatment. The results of the former are :—

Cured or much improved ..	21·5 per cent.
Improved	48·8 ,, ,,
Slightly improved	20·4 ,, ,,
Not improved	9·3 ,, ,,
Total cases treated	270

These results are summarised for a report, not for a paper, and though a table of the type of patient treated is included with a follow-up over three years, no explanation of the terms employed is given. Kessel and Hyman, investigating 33 cases, used very exacting criteria of what constituted a cure by psycho-analysis without any change in environmental factors. They concluded that only five were specifically cured by this method. With modification of the environment, however, in conjunction with analysis, 17 other cases improved. These latter figures correspond roughly to the total results obtained by four different psychotherapeutic methods here.

SUMMARY

1. *Results in different types of cases.*—Fifty cases of functional nervous disorders were treated during the year. Of these 31 improved, 2 got worse, and the others remained unchanged. The results may be grouped as follows :—

Anxiety states improved ..	16 out of 24
Depressives ,, ...	9 ,, ,, 11
Obsessionals ,, ...	1 ,, ,, 3
Hysterics ,, ...	4 ,, ,, 6
Frigidity ,, ...	1
Schizophrenics failed to improve	4
Behaviour problem improved considerably ..	1

2. *Methods employed.*—Improvement was noted in 7 out of 10 cases treated analytically, in 12 out of 25 treated by psychological talks, in 11 out of 16 treated by reassurance and medicine, and in 2 out of 2 treated by suggestion.

3. *Prognosis.*—(*a*) The severity of the attack appeared to bear no relation to response to treatment. (*b*) Domestic, financial, and business worries seemed to play no significant part in determining the outcome of the treatment of a neurotic condition not specifically caused by one of these factors. (*c*) Sex life was unsatisfactory in 50 per cent. of cases who failed to improve, compared to 14 per cent. of those who did. Worry over masturbation was often present. (*d*) Obsessional, hypochondriacal, egotistical, and somatic features make the prognosis worse.

Conclusion.—From the small number of cases investigated it appears that psychotherapy is of value, since approximately two-thirds of the cases improved. There is no evidence to show that any one method of treatment was predominantly successful over the others, but each has its successes. At present the choice must be a matter for individual judgment and predilection. Nevertheless, the results of investigating prognosis in relation to character give some indication of the type of person most likely to respond to treatment, and give some guidance about the advisability of spending much or little time on a given patient.

I should like to thank Dr. Edward Mapother for kindly allowing me to make use of the material derived from patients attending the Maudsley Hospital.

---

CLINICAL TRIALS WITH A NEW ANTITYPHOID SERUM *

By A. Felix, D.Sc. Vienna
MEMBER OF SCIENTIFIC STAFF, LISTER INSTITUTE, LONDON

In experiments on mice, published in The Lancet[1] last year, it was established that antityphoid sera containing O and Vi antibodies exert two separate and distinct effects, viz :—

(*a*) The Vi antibody confers protection against infection with highly virulent strains of *B. typhosus*, by suppressing the multiplication of the organisms.

(*b*) The O antibody appears to be chiefly responsible for effecting the neutralisation of the endotoxin of *B. typhosus*.

It was concluded that the efficacy of a therapeutic antityphoid serum would depend on the presence in it of both these antibodies.

Thanks to facilities granted by the Colonial Office and by the Government of Palestine, I have had the opportunity of testing on a number of typhoid patients whether the two effects, established in prophylactic experiments in mice, are demonstrable also in therapeutic trials in man.

Antityphoid sera (Nos. 1 and 2) from two horses were used in this investigation. They were prepared in collaboration with Dr. G. F. Petrie and his colleagues at the serum department of the Lister Institute at Elstree. In addition, the serum from a normal horse was used for the treatment of a number of control cases. The antibody content of the sera, determined by agglutination, and the results of protection tests in mice are shown in Table I. The details of the mouse protection tests are omitted. The table only indicates that the two antityphoid sera possessed both protective power against infection with live organisms and neutralising power against the toxic effect of a dead vaccine of *B. typhosus*. Normal horse serum had no effect in either of these capacities.

---

* Report to the governing body of the Lister Institute and the Colonial Office under whose auspices the clinical trials were carried out in Palestine.

[1] Felix, A., and Pitt, R. M.: The Lancet, 1934, ii., 186.

TABLE I

—	Antityphoid serum.		Normal horse serum.
	No. 1.	No. 2.

O titre	20,000	40,000	200
Vi titre	400 + +	400 +	20 ±
Protection of mice—			
Against infection with live organisms ..	+	+	—
Against the toxic effect of dead vaccine ..	+	+	—

NATURE OF THE TRIALS

The three sera were used unconcentrated and the standard dose for adult patients was 50 c.cm. administered by the intramuscular route. In severe to very severe cases this dose was given on three consecutive days—i.e., a total of 150 c.cm. of serum was injected intramuscularly. In cases of extreme severity (patients actually moribund or in a desperate condition) the serum was administered intravenously, again employing 50 c.cm. as the routine dose, which was repeated twice or three times at intervals of 24 hours, making a total of 150 c.cm. or 200 c.cm. per case. According to the history as regards previous serum treatment the intravenous injections were either given without particular precautions or the patients were desensitised by injecting first 0·1, 0·2 and 0·5 c.cm. at intervals of half an hour and then the full dose of 50 c.cm.

The total number of typhoid patients treated in Palestine during October–November of last year and the routes of administration of the serum are shown in Table II. The Table shows that most patients were adults. Only 9 of the 60 patients were children below fourteen years. The dosage for children was according to the following scheme:

TABLE II

—	Patients treated with—	
	Antityphoid serum.	Normal horse serum.
Intramuscularly	32	14
Intravenously	10	3
Intrathecally	1	—
Total	43	17
[Children below 14 years] ..	[6]	[3]

Children below 5 years	10 c.cm.
,, 6–9 ,, ...	20 ,,
,, 10–14 ,, ...	30 ,,
,, over 15 ,, ...	*50 ,,

* Full dose for adults.

It is further seen from the Table that the number of control cases, treated with the normal horse serum, was much smaller than that of the patients treated with antityphoid serum. As soon as the difference between the results following the injections of the two types of serum became evident, the physicians in charge of the patients could not be induced to continue the use of the control serum.

The patients were not subjected to the treatment indiscriminately. They were selected with a view to exclude mild cases and those of moderate severity. The procedure was to class each case before the beginning of the serum treatment under the headings "severity of toxæmia" and "severity of pyrexia," and from these two criteria the "total severity" was derived. After the injections the "effect on toxæmia" and the "effect on pyrexia" was assessed and recorded separately.

The great majority of the patients came from the Jaffa-Telaviv district where the incidence of typhoid fever was still high during October–November, 1934. Table III. gives the exact figures.

TABLE III

Locality.	Hospital.	Physicians in charge.	Patients treated with—	
			Anti-typhoid serum.	Normal horse serum.
Jaffa ..	Government Hosp.	Dr. R. Reitler.	25	9
Telaviv ..	Municipal Hosp., "Hadassah."	Drs. M. Levontin and W. N. Wolff.	12	4
Jerusalem	Government Hosp.	Dr. N. Hamzeh.	3	4
,,	German Deaconness Hosp.	Dr. N. T. Canaan.	3	0
	Total		43	17

Uniformity in classifying the cases with regard to their severity was assured by the fact that 50 patients out of a total of 60 were treated in two hospitals under the care of physicians with particular experience of typhoid fever. It was also facilitated by the fact that in most cases the serum treatment was begun during the second or third week of the illness with the symptoms of the disease fully developed. The relevant data are recorded in Table IV.

TABLE IV

Serum treatment commenced during—	Patients treated with—	
	Antityphoid serum.	Normal horse serum.
First week	7	1
Second ,, ...	25	12
Third ,, ...	6	3
Later than third week..	5	1
Total	43	17

RESULTS

The results of the serum treatment observed in the 17 control cases can be dealt with very briefly. Following the intramuscular or intravenous injections of normal horse serum there was in no instance any change in the toxæmic symptoms of the patients. In some cases the fever was lowered, but this effect was only temporary, and after a few days the temperature rose again. The general condition of most of the patients treated with normal serum was rather worse than it had been before, and this caused the physicians to discontinue its use early in the course of the investigation.

The effects of the treatment with the two antityphoid sera, on the other hand, were quite different. To avoid reproduction of a considerable number of individual case-charts I have attempted to summarise the results in Table V. It is seen that the series of 43 cases treated with antityphoid serum includes only 1 case classed as "mild" and 9 of "moderate severity," whereas 21 cases are designated as "severe or very severe," and 12 as "extremely severe." The last group is composed of patients whose condition before the commencement of the serum treatment was considered as desperate or who were actually moribund.

TABLE V.—*Effects of Treatment with Antityphoid Sera Nos. 1 and 2*

Clinical course.	Cases treated.	Effect on— Toxæmia.		Effect on— Pyrexia.		Died.
		+	—	+	—	
Mild	1	0	0	1	0	0
Moderately severe ..	9	3	0	6	3	0
Severe or very severe	21	15	3	11	10	0
Extremely severe ..	12	6	6	5	7	5
Total	43	24	9	23	20	5

It has been mentioned above that each case was classed separately under the headings "severity of toxæmia" and "severity of pyrexia," and that a "total severity" was derived from these two criteria. For the sake of simplicity this "total severity" alone is indicated in the first column of Table V., whereas "effect on toxæmia" and "effect on pyrexia" are recorded separately. The symbol + denotes a marked favourable effect, and — indicates that there was no effect. In each subgroup the sum of the two figures recorded under the heading "effect on pyrexia" is equal to the total number of cases treated. Under the heading "effect on toxæmia," however, the sum of the two figures is, in the first three subgroups, smaller than the corresponding total number; the difference indicates the number of cases without marked toxic symptoms.

Table V. shows that the effect on the toxic symptoms was stronger and more regular than that on the fever. Out of the total of 43 cases, 33 had definite toxic symptoms of varying degrees up to complete stupor and severest status typhosus. Of these 9 cases only remained uninfluenced by the serum treatment, whereas in 24 cases the toxic symptoms ceased, usually after the second or third dose of serum, and did not reappear. On the other hand, the fever was clearly shortened and definitely suppressed only in 23 cases, whereas 20 remained either entirely uninfluenced or showed merely temporary lowering of the fever, similar to that observed in the control group of cases treated with normal serum.

When the different subgroups in Table V. are considered separately, it is seen that with the increasing severity the numbers of failures increase under both headings. This finally led to the application of the intravenous route instead of the intramuscular injections which had been used throughout the greater part of the trial. The effect both on the toxæmic symptoms and on the fever was very much stronger following intravenous administration. However, it will be remembered from Table II. that only 10 of the 43 patients recorded in Table V. received intravenous injections, whereas 32 were treated by the intramuscular route.

To give an indication of the powerful antitoxic action of the immune serum it may be mentioned that in some instances two or three injections, given intramuscularly or intravenously at intervals of 24 hours, transformed a condition of complete unconsciousness into one of well-being. This effect was most striking in a number of patients whose toxic symptoms disappeared while the fever still continued unabated. The condition sharply contrasted with that observed in some of the patients of the control group, where the non-specific action of the normal serum resulted in a temporary lowering of the fever with the toxic symptoms left entirely undiminished.

It is not possible, without reproducing individual case-charts, to discuss the results in greater detail. The small number of cases treated also does not permit of any calculation of a reduction in the death-rate or in the duration of the fever period. All that can be stated is that a number of patients were justifiably considered as having been saved by the serum treatment, while in a number of less gravely ill patients the fever period was considerably shortened.

Two unusual cases seem worthy of being mentioned specifically. Both patients were treated by Dr. R. Reitler at the Government Hospital, Jaffa.

A woman of 32 developed on the twenty-third day of her typhoid fever meningitic symptoms and severest status typhosus. Lumbar puncture revealed clear fluid under high pressure; 70 c.cm. of fluid was removed and 40 c.cm. of antityphoid serum injected intrathecally, and there was slight improvement. The same procedure was repeated 48 hours later and resulted in definite recovery. The patient was discharged from hospital 14 days after the second injection of serum.

The second case was one of perforation of a typhoid ulcer in a male patient of 20, who left his bed in a semi-conscious condition on the fourteenth day of the disease. Dr. W. E. Thompson, surgeon specialist to the Department of Health, Jerusalem, operated on the patient about 18 hours after the perforation had occurred and administered 80 c.cm. of antityphoid serum directly into the peritoneum. The patient also received 50 c.cm. of the serum by the intramuscular route. He recovered, and the surgeon attributed this to the effect of the serum treatment.

There can be little doubt that the antitoxic activity of the serum is due to the O antibody. The serum No. 2 (see Table I.) with an O titre of 1 in 40,000 acted more strongly on the toxic symptoms than the serum No. 1 with an O titre of 1 in 20,000. To what extent the suppression of the fever is to be attributed to the action of the Vi antibody cannot be answered from the present trial, since there was no control group of cases treated with a serum containing O antibody alone. Assuming that pyrexia is an expression of the multiplication of the invading organisms with consequent production of toxin, we would conclude from the protection experiments in mice with Vi antibody alone that the effect of the latter in suppressing invasion would be most clearly manifested by the degree of fever in the earlier stages of enteric and in relapses. The earlier therefore the case comes under treatment the greater should be the opportunity for the Vi antibody to exercise the invasion-suppressing function so clearly exhibited in the mouse experiments. It is proposed in future clinical trials to compare a pure anti-O serum with the serum we have been discussing, containing both O and Vi antibodies.

However, the main object of the present investigation was to establish in therapeutic trials in man whether or not some action on the toxic symptoms and on the fever was exercised by the antityphoid serum. It would appear that the answer to this question is in the affirmative.

I wish to express my gratitude to the Colonial Office and to the Department of Health of the Government of Palestine for the facilities granted for carrying out this investigation and for the hospitality extended to me in Palestine. Dr. R. Reitler, medical officer, Government

Hospital, Jaffa; Dr. M. Levontin and Dr. W. N. Wolff of the Municipal Hospital, "Hadassah," Telaviv; Dr. N. Hamzeh, medical officer, Government Hospital, Jerusalem; Dr. N. T. Canaan of the German Deaconness Hospital, Jerusalem, have been in charge of the patients treated. It was only their kind and most efficient coöperation that made this investigation possible. I am glad of this opportunity of thanking all of them.

SURGICAL CLOSURE OF TUBERCULOUS APICAL CAVITIES

BY W. H. C. ROMANIS, M.Chir. Camb., F.R.C.S. Eng.
SURGEON TO ST. THOMAS'S HOSPITAL AND THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST; AND

T. H. SELLORS, D.M., M.Ch. Oxon., F.R.C.S. Eng.
ASSISTANT SURGEON TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, QUEEN MARY'S HOSPITAL, AND THE ROYAL WATERLOO HOSPITAL

THE problem of the surgical closure of tuberculous apical cavities is one which is being seriously considered by surgeons at the present time, the more so as the value of total collapse of one or other lung by major surgery has become fully established. Tuberculous disease with cavitation which is confined to the apex is frequently seen, and it is naturally felt that the collapse of the whole of one lung by means of a total thoracoplasty may be a severe and unnecessary price to pay when the disease is localised. This is the main reason for the determined effort which has been made to produce a successful apical collapse without interfering with the rest of the lung.

We propose to deal with complete thoracoplasty in a later paper, but there are certain aspects of this major procedure which have a definite bearing on partial apical operations. Thus, its use should be confined to chronic fibrosing and cavernous cases in which pleural adhesions (either complete or partial) preclude the employment of artificial pneumothorax. As a general rule total thoracoplasty is applicable only to those cases in which there is no active disease in the opposite lung; moreover, this operation is a severe one which usually has to be performed in two stages (unpleasant though this is for the patient), and which involves a certain amount of shock and some, albeit slight, permanent deformity. To a certain extent these restrictions apply to localised apical operations, though in considering their indications and contra-indications we shall see that the restrictions are not quite so narrow.

In many cases of upper zone cavitation where an artificial pneumothorax has failed, or even as a complement to artificial pneumothorax, phrenic avulsion is performed. This is clearly an incomplete operation, but though its main effect is usually upon the base of the lung, it may also have a distinct beneficial influence upon the apex (see Fig. 1). It must be admitted that the effect on apical cavities is not as a rule very great, yet the operation is nearly always worth a trial on account of the minimal risk and discomfort associated with it. It can always be performed under a local anæsthetic, and need only entail the patient being in bed for a few days.

INDICATIONS FOR APICAL SURGERY

The type of case in which localised surgical procedures have seriously to be considered is nearly always one in which there are cavities in the apex, and where pleural adhesions prevent a complete artificial pneumothorax. The indications for the selection of cases are, in general, the same as those for a total thoracoplasty; but as we are now dealing with a partial operation in which a considerable area of undiseased lung is going to be left intact and functioning, a greater degree of latitude can be allowed. Moreover, these operations are responsible for much less shock and disability than is caused by a complete thoracoplasty. In the case of the total operation, the whole of one lung is permanently and irrevocably put out of action—a situation that does not apply to partial procedures. Thus, whereas no wise surgeon would countenance a complete thoracoplasty if there was any suspicion of active disease in the opposite lung, it is quite possible, and at times advisable, to produce apical collapse even when it is known that the opposite side is affected. In certain cases of bilateral apical cavitation (of a chronic type) it is perfectly feasible and often of great advantage to do a partial operation on both sides, though of course on different occasions.

The chief indications for performing collapse operations on the apex are as follows:—

1. The ideal case is one controlled by general treatment in which there is a single apical cavity without much surrounding fibrosis. Such a patient may feel and appear perfectly well, but the persistence of tubercle bacilli in the sputum, of slight or occasional fever, or of hæmoptysis is sufficient to show that the disease is not arrested. It is quite certain that the patient will never be cured, or even be safe from a spreading infection, until the cavity is obliterated. The prospect of further danger to himself and to others is always present as long as tubercle bacilli are found in the sputum.

When fibrous infiltration is present in bulk round cavities, the chances of any localised apical operation producing effective collapse are mechanically reduced. If the infiltration is extensive, it is more or less impossible, by a localised operation, to collapse only the diseased area, and the advisability of performing a complete thoracoplasty should then be considered.

2. In many more advanced or non-quiescent cases, and even in bilateral cases, there may be an open apical cavity which is acting as a source of infection for the base of the same lung or for the opposite lung as a whole. The outlook is here not so good, but it is often wise to close the cavities by surgical means, as it often happens that the patient's general resistance, supplemented by appropriate general treatment, will be able to deal with the disease in uncollapsed zones. This constitutes a group of cases from which the number selected for surgical treatment will obviously depend on the views of the physician or surgeon concerned.

POSSIBLE DANGERS AND COMPLICATIONS

Though the dangers, complications, and unpleasantnesses of these partial operations are far less than those of a total thoracoplasty, they nevertheless do exist. There is a certain amount of shock to be reckoned with, but this can be greatly diminished by suitable preparation, proper anæsthesia and, above all, by quick and gentle technique. It is indeed remarkable how slight the shock often appears to be in these tuberculous patients, and how well the procedures are tolerated.

It should also be remembered that in closing an apical cavity by surgical means some pus and active bacilli may be squeezed out, and there is the possibility that they may be inhaled into the base of the lung on the same or even the opposite side. This holds equally well in the performance of a total thoracoplasty, and is used as an argument for doing the lower stage first when the operation is being done in two stages. There is no doubt that a preliminary phrenic avulsion greatly reduces the chances of an aspiration of this kind into the base of the lung, and with this precaution we personally have never seen any evil results due to an aspiration infection following upon an apical collapse.

The rupture of an unduly rigid or brittle-walled cavity as a result of uneven pressure during its collapse is a possibility. This complication may be guarded against by care and gentleness, and by making the extent of the operation and subsequent collapse slightly greater than that required just to cover the cavity.

Occasionally a spread of the disease or activation follows on the operation. When this occurs it is probably due to faulty anæsthetic methods, to an active lesion having been overlooked, or perhaps to an increased and too great functional strain being placed on the intermediate zone of lung tissue as a result of the collapse.

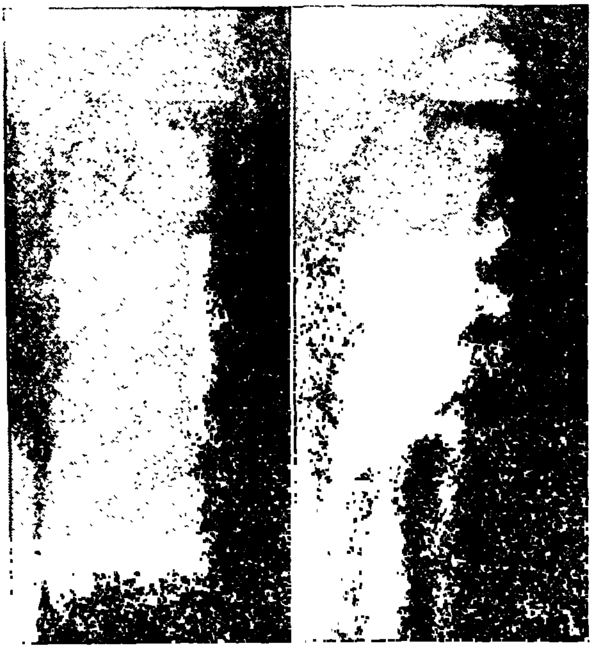

FIG. 1.—Diminution in size of an apical cavity following phrenicectomy. In the left-hand radiogram a large cavity is seen situated immediately under the right clavicle with infiltration spreading out to the periphery. The right-hand photograph shows the condition after phrenicectomy. The right diaphragm is considerably raised, while the cavity is slightly higher placed and shows a reduction in size.

Failure to obtain complete collapse of a cavity is unusual, but it may be seen either when the walls of the cavity are very stiff, or when it is situated especially close to the mediastinum. This nearly always means that the wrong operation has been selected, or that the operation has been incompletely performed, an insufficient number or inadequate length of rib having been removed. One annoying result of this complication is that the cavity may remain open and more or less healthy lung tissue around it be collapsed, and then further operation will have to be resorted to before the cavity is collapsed.

Technical difficulties and dangers undoubtedly exist in these apical operations. Removal of the first rib should be as complete as possible (see below), and the dissection to free this structure is fraught with the risk of injury to important anatomical structures in relationship with it. The avoidance of serious damage can only be effected by experience, the necessary skill, and perhaps with the aid of a few special instruments.

OPERATIVE PROCEDURES

Phrenic Avulsion and Phrenic Crushing have often been described, and little need be said about them except to point out that though they are minor procedures, easily carried out under local anæsthesia, they are in no sense easy. However many hundred times the surgeon may have exposed the phrenic nerve, he will occasionally meet a case in which the nerve is extremely difficult to find.

In connexion with apical lesions, phrenicectomy by itself, though beneficial, is hardly ever the only operation required. We make a practice of doing it as a preliminary to the more extensive apical operation, very largely with a view to preventing aspiration as described above.

There is little difference between phrenic avulsion and crushing of the nerve, except that the former is permanent and leads to atrophy of half the diaphragm. It is the fibrous atrophied appearance of the hemidiaphragm, occasionally seen at post-mortem months or years after a phrenic avulsion, which has led some physicians and surgeons to advocate crushing of the nerve, with its possibilities of regeneration and less

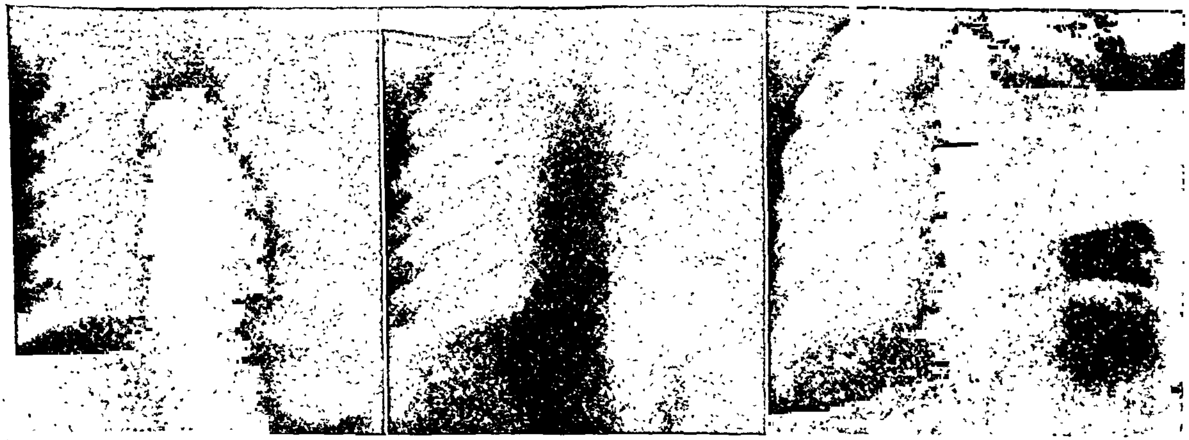

FIG. 2.—Closure of an apical cavity by phrenicectomy and apicolysis. The first radiogram (left) shows a large cavity situated below the left clavicle, and definite upper zone infiltration. There are calcified areas on the right. Following left phrenicectomy the cavity is reduced to about half its former size (middle photograph) and lies higher and more towards the periphery. There was still some cough and T.B. in the sputum. After apicolysis and wax implantation the cavity and apical tissue are completely obliterated (right). The uncollapsed lung showing between the lower limit of the "plombe" and the diaphragm is actually more extensive than appears in the radiogram.

complete atrophy. We are not, however, convinced that this is an argument of any force.

Scalenectomy consists in division of the scalene muscles and has been advocated as a supplement to phrenicectomy in certain cases of apical disease. Its object is to bring about a partial dropping of the first rib, and therefore slight collapse and diminution of movement at the apex. We have performed the operation on several occasions in conjunction with a phrenic avulsion quite easily through a small transverse incision, but we are not convinced that it is one of any real value. Complicated operations for exposure of the scalene muscles and first rib seem to us unnecessary.

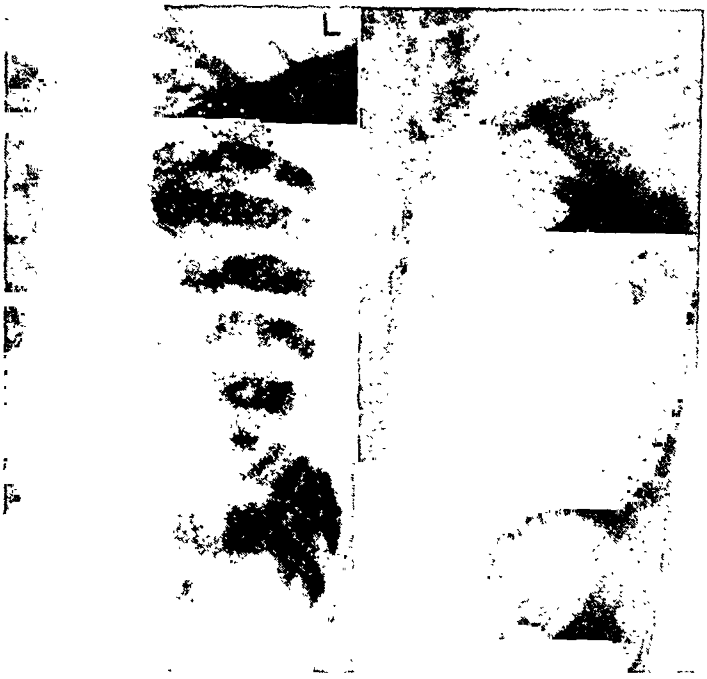

FIG. 3.—Closure of an apical cavity by partial thoracoplasty. The cavity is *situated towards outer part of left lung below the clavicle; there is infiltration of the upper and middle zones of the left lung.* Following a [illegible] *nearly all of ribs 1 to 3, and a length of rib 4)* and appears as a dense streak in the radiogram (right).

There are two main major surgical procedures employed to produce apical collapse. These are very different both in principle and performance. The one consists in the introduction within the ribs, and outside the parietal pleura, of foreign substances to compress and immobilise the lung. This procedure goes by many names, such as extrapleural pneumolysis, apicolysis, plombage, or, on the Continent, Plombierung. For the sake of uniformity we shall refer to it as extrapleural pneumolysis. The second method consists of a partial and specialised form of upper paravertebral thoracoplasty. It is not always easy to foretell which of these two methods will be more effective in any particular case.

1. The first method of *Extrapleural Pneumolysis* is usually done entirely from the front, and is therefore more likely to be effective if the cavities are nearer the front than the back of the apex. No ribs are removed, no deformity is produced, and there is very little shock. Moreover, when paraffin wax is introduced, the lung is not only collapsed and immobilised, but actual pressure is exerted over the cavities. On the other hand, in a certain proportion of cases the foreign material introduced is liable to give trouble after some months or even years. It may start to come out of the wound, and after a long period is completely extruded. In spite of this, the benefit of the operation is usually great, and persists even though all the foreign material has come away. More rarely, the foreign material finds its way into a bronchus and is coughed up without undue harm to the patient.

Extrapleural pneumolysis is based upon the fact, originally noticed in the post-mortem room, that when two layers of pleura are densely adherent to each other it is easier to strip the parietal pleura off the deep surface of the ribs than to separate the two layers of pleura from each other; the lung is far less likely to be torn if this is done. The procedure therefore consists in stripping the parietal pleura off the ribs, in the plane of the endothoracic fascia, for the required distance over the apex. This can be done from behind after the removal of one or two ribs, but the exposure is not good and the amount of stripping and wax introduction which is possible is small. A far better way of doing the operation is to do it from in front without taking out a rib at all. This was first performed in this country by one of us (W. H. C. R.) about fifteen years ago.

For this operation the patient is laid on his back and the upper thorax is slightly arched over a raised bar on the table. A long transverse incision is made from the sternal edge to the anterior axillary border between ribs 2 and 3, or, if preferred, between ribs 1 and 2. The fibres of the pectoralis major muscle are split along the line of the incision and the intercostal space exposed. The intercostal muscles are carefully incised down to the level of the parietal pleura which must be exposed without being damaged. At this stage it may be necessary to introduce some form of rib-spreader, but this is hardly ever required, and if used is liable to tear the pleura. With great care the pleura is then pushed off the deep surface of the ribs, and the dissection is carried up to the apex, along the front and sides of the lung and over to the back of the lung for as wide an area as may be required. The whole apex and upper part of the lung can then be displaced downwards and centrally, leaving a large extrapleural cavity. The problem then arises as how to fill this space with some substance which will maintain the collapse of the lung.

We have made many experiments during the last fifteen years as to what is the best substance to employ for filling the extrapleural cavity. The pectoralis major muscle can be used, but it is usually not big enough or long enough, and besides it soon atrophies. If a suitable lipoma can be obtained at the appropriate time from an operation on a patient with a negative Wassermann, this can be used with advantage, but these tumours are not easy to come by when required. We have sewn up the incision with an air-tight suture, and filled the extrapleural space with gas, thus creating an extrapleural pneumothorax, but the gas was exceedingly rapidly absorbed from the raw surfaces of the cavity and surgical emphysema was a very common sequel. We have also inserted a rubber balloon into the cavity and subsequently blown it up before the wound was closed; this produced excellent immobilisation and collapse, while it was in position, but it could not be left in indefinitely as the air was liable to leak out and the rubber to perish. It was found that, in the majority of cases, paraffin wax was the best substance to use. This can be had at any melting-point required, and we generally employ it at a melting-point of about 55° C. It is sterilised and kept hot and liquid at the time of operation; then when required it is poured into a basin of cold sterile water. It sets quickly into a pliable jelly, which can be moulded and forced into every crack and cranny of the cavity. After the cavity has been completely filled the wound is sutured as carefully as possible without drainage. Care should be taken that the paraffin does not soil the edges of the muscle or skin, since this may interfere with healing. Healing by first intention is almost the invariable rule though, as we have already said, there is an occasional tendency for the wax to come out after some months (Fig. 2).

In one instance a large lump of wax slipped down within the ribs and found its way into unobliterated pleural sac at the base of the lung. This did not seem to do any great harm, and the result was still quite good. One conspicuous advantage that this operation possesses over all others lies in the fact that, in addition to obtaining collapse of lung, actual pressure is also exercised.

2. *Apical Thoracoplasty.*—The alternative operation to wax implantation is sometimes known as an apical or partial upper thoracoplasty. The nomenclature has unfortunately become rather confused by certain authorities also referring to this as apicolysis—a term which we prefer to reserve for the previous operation.

In principle the procedure is very similar to the upper half of the ordinary total paravertebral thoracoplasty; but more attention is paid to the first and second ribs from which considerably longer lengths are removed. The number of ribs that have to be removed depends entirely upon the size and situation of the cavities. It is probably never sufficient to remove the first rib only, and usually we remove good lengths of the upper three or four ribs, though occasionally five or six may be necessary. It is important to take away enough rib to get well below the lower limit of the cavity as shown in the X ray picture, while the abrupt nature of the collapse at the lower limit is eased, and the patient made more comfortable by excision of short lengths of a rib or two below; this gives the collapse a graded effect. This operation, properly performed, will produce practically complete collapse of the apex with little or no visible deformity. The collapse can be rendered even more effective by the addition of a certain amount of extrapleural pneumolysis, which can be simply carried out by blunt dissection after ribs have been removed.

The operation can be performed through an incision in the axilla, or through a high posterior J-shaped incision. We much prefer the latter method, and make a practice of freeing the scapula and carrying it well forward so as to ensure good exposure of the upper ribs. The whole of the first rib as far forwards as its cartilage should be removed in every case. This apparently difficult manœuvre is simplified by means of a special first rib elevator, and by a special method of stripping the rib from the highly important and easily damaged structures that lie in close relationship with it. The problem of freeing the first rib with safety is, in fact, rather similar to that of elevating the dura mater from the base of the skull in approaching the Gasserian ganglion and fifth nerve-root.

There are several methods of approach to the first rib, such as those suggested by Lauwers and Graf, but we have found the preceding by far the most simple, and one in which as small or as large an operation as required may be performed (Fig. 3).

STERILITY AND PSYCHONEUROSES FOLLOWING LUMBAR SYMPATHECTOMY

By Arthur F. Hurst, M.D. Oxon., F.R.C.P. Lond.
SENIOR PHYSICIAN TO GUY'S HOSPITAL

Lumbar sympathectomy is an operation which is undoubtedly of value in the treatment of certain vascular disorders affecting the legs and of intractable pelvic pain. In the last few years it has been performed with increasing frequency for megacolon, including Hirschsprung's disease, although, as I have shown in a paper in the *Guy's Hospital Reports* for July, 1934, it is very doubtful whether it can accomplish anything which cannot be attained by non-operative measures. It has also frequently been performed for constipation, though I have not seen a single case in the last twenty years in which medical treatment has proved sufficiently unsuccessful to warrant the performance of an operation of any kind. As an example of how recklessly the operation is sometimes undertaken, I may quote from a recent paper by S. H. Harris on renal sympathectomy. After saying very properly that "there is ample evidence to prove that the indiscriminate use of renal sympathectomy merits nothing but condemnation," he adds that in certain cases, when constipation is prominently associated with the renal disorder, "lumbar ramisection may be advantageously performed through the same incision," as "it adds only a very few minutes to the time of the operation." Lastly lumbar sympathectomy shows signs of replacing appendicectomy as the operation performed by the unwise surgeon who does not like to close the abdomen without doing anything if he finds no organic disease at an exploratory laparotomy.

The object of this paper is to make it more widely known that abdominal sympathectomy invariably leads to one serious complication in men. Time will show whether any other undesirable sequelæ may occur.

The first reference to the effect of sympathectomy on the sexual functions appeared in a paper by Learmonth in *Brain* (1931) on the Neurophysiology of the Urinary Bladder in Man. He showed that when the presacral nerve is stimulated a cloud of seminal fluid and prostatic secretion is poured into the prostatic urethra as a result of contraction of the seminal vesicles, ejaculatory ducts, and muscular septa of the prostatic gland. Consequently sympathetic neurectomy in males results in the abolition of ejaculation, although the sexual act is otherwise normal and the psychological orgasm is unaffected. In the following year, in a communication on the Innervation of the Bladder to the neurological section of the Royal Society of Medicine, he again referred to these observations and added that male patients must obviously be warned before operation that it will be followed by sterility although not by impotence. Lastly, in a paper on the Surgeon and Pain in the *British Medical Journal* for Jan. 12th of this year, he remarks that the only really undesirable sequel of presacral neurectomy is sterility, and adds that fortunately it appears to have no effect on the sexual functions of women. As, however, most of the females upon whom the operation has hitherto been performed have been elderly women in whom the sexual functions are already in abeyance, it is still possible that these functions may be seriously impaired if the operation is performed in girls and young women; that fortunately Hirschsprung's disease is very rare among the former, though megacolon is not uncommon among the latter. The only other reference to sterility following sympathectomy which I have been able to find is in a paper by Paterson Ross (1934) on Prognosis of Raynaud's Disease, in which he states that after bilateral lumbar gangliectomy male patients, though still potent, are likely to become sterile.

Only those surgeons who read either *Brain* or the transactions of the neurological section of the Royal Society of Medicine may happen to have seen the two casual references to the subject in Learmonth's paper on the Surgeon and Pain, and Paterson Ross's on the Prognosis of Raynaud's Disease; they are likely to be still ignorant of this important sequel of the operation.

It is clear that lumbar sympathectomy should only be performed in males when a condition is present which is likely to receive sufficient benefit to compensate for the unavoidable sterility which will develop. I doubt whether it is ever justifiable in boys with Hirschsprung's disease. In the eight cases I have seen since the war non-surgical treatment led to improvement just as great as that claimed for sympathectomy. It is certainly a very serious thing to sterilise a boy, even with his parents' consent. Whether the Statute of Limitations will protect a surgeon when a sterilised boy, whose parents were not warned, reaches adult life is an interesting medico-legal question. There can be no doubt that the operation should never be performed on an adult male without his written consent after he has been told of the effect it will have on his sexual functions. If he knows what to expect he is also very unlikely to develop psychoneurotic symptoms as a result of the loss of emission, as his enjoyment of the sexual act will remain unimpaired and, if he already has as many children as he wanted, he may regard the operation as incidentally affording a safe means of contraception.

I have seen two cases in which the impairment in sexual functions following lumbar sympathectomy in men was followed by serious psychoneurotic symptoms.

CASE 1.—A mechanic, aged 47, had a left lumbar sympathectomy performed in September, 1933, followed six weeks later by a similar operation on the right side for bilateral thrombo-angiitis obliterans, which had been giving rise to intermittent claudication for six years in the left leg and one year in the right. Some improvement in the condition of the legs ensued. When he returned home after the operation he noticed that he was unable to get an emission, though his sexual functions were otherwise normal. He was much worried about this, and was still more upset when for the first time, on March 15th, 1934, apparently as a result of over-anxiety, he failed even to get a satisfactory erection. A severe headache developed, which had disappeared by the following morning. It returned at midday in an aggravated form, and half an hour later he became dizzy with blurred vision. He had been unable to eat his lunch owing to extreme dryness of his mouth. At 3 P.M. he lapsed into what he described as unconsciousness, but during this time he was very abusive to his wife. He regained consciousness an hour later, but still had blurred vision. The eyes of his wife and friends seemed like balls of fire, and he had lost the use of his hands and forearms. At 7 P.M. he went to sleep and woke two hours later quite normal. He was taken to hospital, but was found to have no abnormal physical signs apart from those due to his arterial disease. The attack was regarded as hysterical; he was reassured and discharged on April 14th.

He remained free from attacks until August, when he had one similar to the first. In October he had a third attack in every way like the other two, except that it was accompanied by a homicidal attack on his wife, whereas before he had merely been abusive. He was placed in a mental observation ward, where he remained quiet and mentally clear.

As the patient had never had any symptoms pointing to nervous instability before he discovered that he could not complete the sexual act with the normal ejaculation, it seems extremely probable that the attacks were purely psychogenic, and were a direct result of the impairment in his sexual activity resulting from the sympathectomy.

CASE 2.—A man of 45, married, with three children, had had since childhood abdominal symptoms which were probably the result of a megacolon, though that was not recognised until 1931. For several years he had had an anxiety neurosis for which he had recently undergone a course of psychotherapy. Lumbar sympathectomy was performed in 1932. From that time he found that the sexual act terminated without the occurrence of emission. He became extremely worried about this and thought that he was "losing his manhood." His anxiety symptoms, which had been troublesome enough before, became greatly exaggerated. Unfortunately, also, the operation had failed to produce any improvement in his abdominal symptoms. When it was explained to him that the loss of ejaculatory power was a natural result of the sympathectomy, although this had not been known at the time the operation was performed, he was greatly relieved. It was not the absence of emission which had worried him, as he had as many children as he wished for and sexual desire was unaffected. But the fear that the loss signified some serious change in his nervous system had become an obsession, which was at once removed when he realised that the cause was physical and not psychological.

LEPTOSPIRAL JAUNDICE AMONG SEWER-WORKERS

BY J. M. ALSTON, M.B., M.R.C.P. Edin.
AND OTHERS

(From Hospitals and Group Laboratories of the Public Health Department, London County Council)

IN July, 1934, there was published an account by Dr. W. Hamilton Fairley[1] of a fatal infection of leptospiral jaundice in a sewer-worker in London, and in the same publication a report was given of serum agglutination reactions which indicated that eight sewer-workers who had previously suffered from jaundice had been infected by *Leptospira icterohæmorrhagiæ.* Since the time of this paper five more London sewer-workers are known to have suffered from jaundice which has been shown either conclusively or circumstantially to be due to the same micro-organism. The present report deals with three of these cases, and also describes the isolation of virulent *L. icterohæmorrhagiæ* from slime in London sewers.

The First Case

The clinical notes have been supplied by Dr. P. J. Watkin (Lambeth Hospital).

A. B., a man aged 52, was admitted to Lambeth Hospital (L.C.C.) on July 3rd, 1934. He had been employed intermittently during the previous five years as a flusher in sewers.

The *history* was that he had had pains in the legs for a week before admission, and had been jaundiced for the last four days of that period. There had been during this time occasional vomiting of chocolate-coloured material, in attacks which were sudden and severe. The urine had been dark and the motions clay-coloured but without obvious blood. There had been great loss of appetite, and the patient had sometimes felt very faint. There had been no similar illness previously.

On *admission* the skin and scleræ were deeply jaundiced and the tongue dry and coated. The liver was not enlarged and no ascites nor abdominal tenderness were detected. There was slight pulmonary emphysema, and the heart sounds were indistinct and the rhythm tic-tac. The pupils reacted sluggishly to light and the knee-jerks could not be elicited. Nothing abnormal could be found in the muscles of the calves where pain was complained of.

The *progress* of the case from the time of admission was of gradual and general improvement with decrease of the jaundice, and during the early part of convalescence the patient was extremely weak. Except for a small rise of temperature to an average of 99·6° F. from July 11th to 14th, the course of the illness in hospital was remarkably afebrile.

On July 6th and 10th occult blood was found in the fæces, but on the 13th this reaction was negative, and the van den Bergh test with the blood-serum was of the prompt biphasic type. The result of blood count on July 13th was :—

Red cells ..	2,440,000 per c.mm.	Polymorph	84 %
White cells ..	15,400 ,,	Lymphocytes ..	12 %
Hæmoglobin ..	50 %	Monocytes	4 %
Colour-index ..	1·0		

The appearance of the red blood corpuscles was normal except for slight anisocytosis, and the average corpuscular diameter was 0·8 μ. In the urine bile was present at first, and albumin was detectable in small amount from the time of admission until August 15th.

By August 22nd the jaundice had almost entirely disappeared, and on Sept. 7th the patient was fit enough to leave hospital. He weighed on admission 9 st. 4 lb. and on discharge 10 st. 13 lb.

For *treatment* two doses of novarsenobillon had been given—0·35 g. on July 10th and 0·6 g. on July 16th. Aspirin and a mixture containing potassium citrate were also prescribed.

BACTERIOLOGY

Bacteriological investigations were performed at Lambeth Group Laboratory (Dr. J. A. Braxton Hicks) and Archway Group Laboratory (Dr. Alston).

On July 9th a microscopical examination, by dark-ground illumination, was made of the deposit of urine after centrifuging, and several immobile distorted spiral bodies were seen which were suspected of being leptospira. A large amount of this deposit was injected into the peritoneal cavity of a guinea-pig, which died 11 days later and then showed generalised jaundice and numerous hæmorrhages in the subcutaneous tissues and internal organs. Actively motile leptospira were seen in a specimen of the blood examined by dark-ground illumination and the organism was obtained in pure culture in Noguchi-Wenyon medium. In a specimen of blood taken from the patient on July 9th and in urine and blood obtained on the 16th, no evidence of leptospira was found microscopically or by animal inoculation.

Serum of blood obtained on July 9th and 16th was examined by Major H. C. Brown at the Wellcome Research Institute, and he found that both specimens gave a strongly positive adhesion test[2] with a London human strain (Jackson) of *L. icterohæmorrhagiæ*, indicating that the serum contained antibodies specific to that organism. It may be noted that very recently[3] the adhesion test has been correlated with and found equally sensitive to the agglutination test described by Prof. Schüffner.[4]

The Second Case

The clinical notes have been supplied by Dr. J. H. Simmons (St. Alfege's Hospital).

C. D., a man aged 35, was admitted to St. Alfege's Hospital (L.C.C.) on July 11th, 1934. He had been employed for three years as a flusher in sewers.

The *history* of the case was that on July 6th, five days before admission, the illness had begun suddenly—like "influenza"—with pains which started in the lower limbs and gradually extended upwards to the abdomen and between the shoulder-blades. The onset was so sudden that it could be referred to a particular moment while the patient was riding his bicycle. On the following day he had some lower abdominal pain and began to vomit. The vomiting was severe, and the material vomited was dark and may have contained blood. There was no other site of hæmorrhage. Jaundice was noticed the day before admission to hospital. The patient's health had been previously good except for chronic constipation. So far as he knew he had not recently suffered any abrasion or cut of the skin or a rat-bite. He stated that some of his workmates had been jaundiced, but so far as he knew they had not been ill enough to go to hospital.

On *admission* the patient was a well-developed man with intensely jaundiced skin and conjunctivæ. He was moderately ill, with a temperature of 100° F. and a pulse-rate of 116. The tongue was dry and coated, the gall-bladder tender, the liver not enlarged, and the spleen not palpable. No purpura or petechiæ were present. No pathological state was detectable in the heart or lungs. The urine contained bile-pigment in large quantity, a trace of albumin, and no sugar or acetone. The stools were dark.

The *progress* was that for the first few days the patient suffered from continual vomiting and dehydration, but these conditions were relieved by enemata followed by rectal injections of glucose saline solution. The general condition then improved, and temperature and pulse-rate had returned to normal on the fifth day. The jaundice and presence of bile in the urine took about a fortnight to subside. On the fifth day in hospital a transient erythematous rash was seen, mainly on the limbs. The patient left hospital on August 2nd.

The result of a blood count on July 12th was :—

Red cells ..	5,000,000 per c.mm.	Polymorph	87 %
White cells ..	17,000 ,,	Lymphocytes ..	9 %
Hb.	100 %	Monocytes	4 %
C.I.	1·0		

The blood-urea was 125 mg. per 100 c.cm. on July 12th, 145 mg. on the 14th, and had returned to normal limits by the 19th. The van den Bergh reaction gave an "immediate direct" positive result up to July 19th, and a delayed direct positive result on July 27th and August 8th, the number of units by the indirect reactions was highest—54—on July 14th and was 4 on August 8th.

BACTERIOLOGY

Dr. E. N. Allott (Lewisham Group Laboratory) and Dr. Alston (Archway Group Laboratory) investigated the bacteriology of this case. On July 12th and 23rd the urine was examined for leptospira by dark-ground illumination methods but none was seen. A guinea-pig was injected intraperitoneally on July 12th with the deposit from centrifuged urine, but no evidence of infection was detected. Specimens of blood-serum were obtained on August 4th and Sept. 12th, and both gave a strongly positive reaction in the adhesion test with *L. icterohæmorrhagiæ*; these results were kindly confirmed by Major Brown. In the case of the second specimen, the reaction could be obtained in dilutions of the serum up to 1/160.

The Third Case

The clinical notes have been supplied by Dr. G. C. Pether (St. Charles' Hospital).

E. F., a man aged 52, was admitted to St. Charles' Hospital (L.C.C.) on Nov. 18th, 1934. He had been employed since June, 1934, in relaying sewers for which he worked in very old open trenches, and the sewers contained much slime and silt. He had done tunnelling work before, but not for some years. During October he cut a finger of the left hand on the edge of a broken drain-pipe during employment, and this wound was dressed and he continued working.

Dr. J. Butler, Hammersmith, informs us that on Nov. 11th the patient felt very hot, and on the next day complained of pains all over and severe headache. There was a slight cough and a few bronchial râles, but no other physical signs of disease. The temperature was 102° F. Sodium salicylate was prescribed. On the 13th and 15th the patient had been sleeping badly and the medicine was being vomited, even when diluted. On the 15th a little milk was retained and Medinal grs. 5 was prescribed. The temperature on those days was 99·6° and 99°. On the 17th the urine was dark red with blood, and a little blood was coughed up and the patient complained of itching, and jaundice was probably present. The temperature was 99·2°. On the 18th the patient was jaundiced all over, there was much blood in the urine, and epistaxis and hæmatemesis occurred. The liver was enlarged and the stools were clay-coloured for the first time.

On *admission* delirium and slight twitchings were present and the temperature was 98°. On the 19th the condition was almost the same, the conjunctivæ were much injected, epistaxis had recurred, and blood and bile were detectable in the urine. Blood was vomited, and both altered and fresh blood was present in the stools. The result of a blood count was: red cells 2,670,000; Hb., 50 per cent.; C.I., 0·9; leucocytes, 25,000 (polymorphs 91 per cent.). On the 21st the condition became worse, restlessness and twitchings were more marked, and an estimation of blood-urea showed 480 mg. per 100 c.cm. On the 22nd the patient died.

At the time of admission the patient was questioned about the possibility of contact with rats in the course of his work. He appeared to be sufficiently rational to appreciate the question and denied the likelihood of any such contact. In view however of the severe and unusual symptoms which developed two or three days before death the possibility of leptospiral jaundice was entertained, and a specimen of blood-serum was examined by Major H. C. Brown and the leptospiral adhesion test was found strongly positive. On the result of this test leptospiral antiserum was immediately ordered, but it was not received until after the patient's death.

POST-MORTEM FINDINGS

The following is an account of investigations by Dr. W. G. Barnard (Central Histological Laboratory, Archway Hospital):—

Autopsy.—Dark canary-yellow jaundice of skin and less severe of all serous surfaces; well-nourished, well-developed muscular man. A few small recent abrasions on skin of chest probably due to scratching; laceration of nail of middle finger of left hand extending throughout its length. Pale flabby myocardium. Moderate general and coronary atheroma. Slight broncho-pneumonia, œdema, and congestion of posterior parts and bases of both lungs. Enlarged flabby olive-green liver. Bile-ducts patent. Thin dark-green bile in gall-bladder. Congestion of spleen. Enlarged kidneys with swollen jaundiced cortex and slight hæmorrhage in pelvis beneath capsule and in perirenal fat. Slight hæmorrhage in fatty tissue round both adrenals. A few scattered hæmorrhages in mucosa of stomach and throughout intestines. Pale greenish-brown urine in bladder. A few minute hæmorrhages in mucosa of bladder. Slight diffuse subdural hæmorrhage and a few petechiæ in cortex of œdematous brain. Middle ears and mastoids clean.

Histology.—The following organs were examined histologically: liver, kidney, spleen, adrenal, lung, brain, pituitary, and parathyroid. The sections were stained by Ehrlich's hæmatoxylin and eosin, by van Gieson's method, and liver, kidney, and adrenal sections were stained by Levaditi's method for spirochætes. The macroscopic findings were confirmed. In addition there was an excess of polymorphs in the spleen, and slight fibrosis of the anterior lobe of the pituitary. The changes in the liver and kidney warrant a more detailed description.

In the liver the chief changes consisted of jaundice and degeneration of cells in the central parts of the lobules and in those of the mid-zonal regions. The jaundice was less severe than that expected from the naked-eye appearance, and the degeneration consisted of fatty change and necrosis of scattered individual cells. There were patches of subacute inflammatory infiltration of the interstitial tissue of the kidney, the reaction consisting of plasma cells, lymphocytes, and a few polymorphs. The epithelium of the convoluted tubules was everywhere degenerate, many of the cells contained bile-pigment, and in many tubules there were bile casts.

Comment on autopsy.—Definite spirochætes were not found, but particularly in the kidney and adrenal there were strictures resembling fragmented spirochætes and many granules that might well have been the remains of spirochætes. The slight degree of degeneration and necrosis of the liver, the widespread subacute interstitial infiltration and degeneration of the epithelium of the kidney, together with the severe general jaundice, make up a characteristic picture, and one that is not found in any other disease.

BACTERIOLOGY

Material obtained at autopsy was examined bacteriologically at St. Mary Abbots Group Laboratory (Dr. G. W. Goodhart) and Archway Group Laboratory (Dr. Alston). Blood, urine, and emulsions of liver and kidney tissue in which no leptospira could be seen microscopically were inoculated intraperitoneally each into two guinea-pigs, but no certain evidence of infection, by temperature reaction, clinical signs, or autopsy was obtained in these animals or in others inoculated with their blood and tissues. The patient's blood-serum was found to give a positive adhesion test in dilutions up to 1/160.

Comment on the Cases

Of these three cases the nature of the infection was fully proved in the first, and was made very strongly presumptive in the second by the clinical course and the positive leptospiral adhesion test, and in the third by those features and by the post-mortem findings in addition. In all three cases, also, there was a polymorphonuclear leucocytosis which is constantly found in leptospiral jaundice, and is in contrast with a tendency to leucopenia, and an absolute or relative lymphocytosis which have been observed in epidemic catarrhal jaundice by investigators abroad and in this country.[5]

Two small epidemiological points may be made. Since the fatal case described by Dr. Fairley was of a man who had worked for only three weeks in the sewers, it was thought possible that cases might be found chiefly among the recent recruits to this work, but on investigation the length of service in sewers of the three cases reported above and of other recent cases was of five months to five or more years. Secondly, infection has occurred among both classes of sewer-workmen—building labourers and flushers. The former are much engaged in chiselling out and handling the slime-covered brickwork of the bottom of the sewers from which, as described below, virulent leptospira can be demonstrated, and abrasions of hands often occur. Flushers are not in such close contact with the slime, and obvious skin abrasions are not so frequent. The fact that both types of workers may become infected suggests that the route of infection in some may be by the mucous membranes of the alimentary or respiratory tracts as is believed to occur in persons infected with *L. icterohæmorrhagiæ* after falling into[4] or drinking[6] contaminated water. It may be said that sewer-workers are, in general, instructed to have major abrasions or cuts cleaned and covered, and hot water and soap are provided for them to clean their hands at the end of work and at breaks for food; but in addition to these dangers, there is also the possibility of infection by touching the mouth or nose during work.

Isolation of L. Icterohæmorrhagiæ from Rats and Slime in Sewers

Before the occurrence of the fatal case of leptospiral infection in a sewer-man which was described by

Dr. Fairley, and has already been referred to, it had been decided at the instigation of the Public Health Department, L.C.C., to investigate the possibility that cases of jaundice that had occurred from time to time among sewermen might be due to leptospiral infection. For this purpose some strains of *L. icterohæmorrhagiæ* were isolated from sewer rats and the presence of the organism was sought in sewer slime with which the workmen inevitably come into contact. No effort was made to estimate the proportion of rats caught in sewers from which leptospira could be isolated, because the fact of a varying but often high incidence of infection of rats by the leptospira is known from surveys on rats caught in different situations in several parts of this and other countries; but by the inoculation of guinea-pigs with kidney and liver tissues from rats caught in sewers in eight different parts of London five strains of virulent *L. icterohæmorrhagiæ* were obtained. Four of the strains were obtained by subcutaneous inoculation of guinea-pigs with rat tissues, but in one instance in which intraperitoneal inoculation was used the circumstances of the isolation may be mentioned. In this instance it was thought that a few inactive leptospira were present in a preparation from the rat's kidney examined by dark-ground illumination. A guinea-pig was inoculated intraperitoneally with a suspension of ground kidney tissue and remained alive and apparently well for a period of six weeks and then was killed. No evidence of jaundice, hæmorrhage, or other lesion suggesting leptospiral infection was found at autopsy, and no leptospiras could be seen in preparations of blood, liver, or kidney examined by dark-ground illumination. Another guinea-pig was inoculated subcutaneously with the tissues of the first and it died thirteen days later showing jaundice of the subcutaneous tissues and hæmorrhages in the thoracic and abdominal organs—a typical picture of leptospiral infection. The demonstration of leptospira in the blood and tissues by dark-ground illumination was doubtful, but a pure culture of these organisms was obtained from the blood by inoculation of Noguchi-Wenyon medium.

By a similar technique of inoculating guinea-pigs by subcutaneous injection or by scarification, pathogenic leptospira were demonstrated in a specimen of slime from the floor of a sewer near the spot where Dr. Fairley's patient had been working immediately before his fatal infection, and in another specimen from the outlet of a house-drain into a different sewer. It is worthy of note that in the case of each of these specimens, only one out of two guinea-pigs inoculated in the same way and at the same time succumbed or showed any evidence of infection. Twenty-eight similar specimens of slime from the floor or lower part of the walls of the sewers or from the outlets of drains produced no sign of infection in the animals inoculated with them, and six specimens of the small slimy stalactites which form on the roof and contain chiefly gritty material from the cement of the brickwork did not give rise to any evidence of infection in guinea-pigs. This isolation of virulent leptospira from sewers recalls the isolation of the same organism from slime in a coal-mine recorded several years ago.[7]

In the inoculation experiments described young guinea-pigs of about 300 g. weight were used, but as has just been noted they were clearly unequal in susceptibility to infection by the same route, even although temperature records were not taken for detecting slight non-fatal reactions. In isolating the leptospira from both slime and rat tissues in which the leptospira were probably very scanty, inoculation by subcutaneous injection or, as maintained by C. C. Okell, by rubbing inoculum into scarified skin surface was found more effective than intraperitoneal injection with guinea-pigs of the size used (300 g.), which was the smallest available.

Acknowledgments are made to Dr. P. J. Watkin, Dr. W. D. Wiggins, and Dr. B. Hood, medical superintendents of, respectively, Lambeth, St. Alfege's and St. Charles' Hospitals for permission to publish notes of the cases. Thanks are given to Mr. S. J. Denyer, senior technician at Archway Group Laboratory for assistance.

Clinical and Laboratory Notes

A CHAPTER OF ACCIDENTS IN A CASE OF KALA-AZAR

By A. Piney, M.D. Birm., M.R.C.P. Lond.

ASSISTANT PHYSICIAN TO ST. MARY'S HOSPITAL FOR WOMEN AND CHILDREN, LONDON, E.; HON. PHYSICIAN, ST. PANCRAS DISPENSARY, N.W.

There is a modern prejudice against the publication of single cases, but there are occasions when a patient presents so many points of interest that it is improbable that a series of similar observations could ever be collected. In the present case there was such a concatenation of accidents as is never likely to be repeated.

Mrs. A., aged 39, whom I saw at the request of Major J. R. Yourell, R.A.M.C. (ret.), had been in India in 1929 and again in 1932. During her stay there she had not suffered from any disability other than slight concussion, due to a fall from her horse. When I saw her on July 29th, 1934, she said that she had been feeling unwell for about twelve months, and that she had had an almost persistent evening temperature in the region of 100·6° F. For a time she had been treated for colitis, and in April, 1934, there had been some argument about the palpability of her spleen, but this discussion was stopped because she apparently developed an acute cholecystitis, which was operated on by Mr. E. K. Martin, who found only a distended gall-bladder with no signs of calculus or infection. She was gravely ill but recovered relatively rapidly, although the evening rise of temperature persisted.

When I saw her she was extremely pale; there were a few pigmented patches on the inner sides of the arms; the spleen was firm and slightly tender, extending down as far as the umbilicus. The liver was also enlarged, extending three fingers-breadth below the costal margin. The blood showed:—

Red corpuscles	2,300,000 per c.mm.	Neutrophils ..	70 %
Leucocytes ..	2,000 „ „	Monocytes ..	20 %
Hæmoglobin ..	38 %	Lymphocytes ..	10 %

The clinical and hæmatological characters suggested the possibility of kala-azar, and the patient was seen by Dr. Carmichael Low. A liver puncture was performed, but although many endothelial cells were found in films, no definite Leishman-Donovan bodies were recognised.

Treatment with intravenous Neostibosan was started, and by the end of a week there was distinct decrease in the size of the spleen. On the eighth day there developed great abdominal distension, and enemas, acetylcholine, and Prostigmin failed to cause any improvement. As the condition became definitely worse, Mr. A. L. Abel performed a laparotomy on August 9th, 1934, and found a volvulus of the pelvic colon. At operation there was a small amount of clear fluid in the peritoneum and a peculiar semi-gelatinous thickening of the mesentery. The cæcum was brought to the surface but not opened, as we thought that a "safety valve" might be needed later. She did very well after the operation, although the temperature never settled. At this time there was slight œdema of the ankles. Treatment with neostibosan was continued until 3·0 g. had been given, and on August 29th the spleen was not palpable and the liver did not appear to be enlarged. The œdema of the ankles had slightly increased and, indeed, extended half-way up the calves. The temperature was normal and all looked very promising, especially as the hæmoglobin was now 69 per cent.

On August 10th the temperature started to rise again and œdema of the legs extended right up to the thighs, and at the same time there was much fluid in the abdomen. The next day the right side of the chest was full of fluid, but even so the amount of urine passed was not decreased and there was no albuminuria. The blood-urea level was normal. There was now so much respiratory embarrassment that she was seen by Dr. G. E. Beaumont, at whose suggestion she was given a transfusion and an injection of Salyrgan. It was difficult to find a vein for the transfusion, as so many had been used for the neostibosan and for pre- and post-operative transfusions, but nevertheless it was done. The urine output fell and nothing influenced it. The œdema became enormous, the abdomen was distended with fluid, and both sides of the chest were full. The prognosis seemed hopeless, and this view was confirmed by Lord Horder. So convinced were the nurses of her impending death that the matron of the nursing-home, who was short of space, let my patient's room! In a despairing attempt I injected 5 c.cm. of salyrgan intravenously at a time when the patient was almost unconscious, and within twelve hours she had passed 6 pints of urine and was feeling better. All this time the blood-urea was only slightly raised and there was only the faintest haze of albumin in the urine; casts were absent. She was put on ammonium nitrate and was given several more injections of salyrgan until the œdema had disappeared and she was feeling well; but the temperature never became quite steady, although the evening rise was never above 100°.

For a month all seemed to be going well, although slight œdema of the ankles had recurred. The patient was being kept in the nursing-home only because she was so thin and weak that it was felt better to prolong her stay. Her hæmoglobin was 72 per cent., and her leucocyte count, total and differential, was normal.

Suddenly, exactly one month after her last collapse, she had a violent fit without any prodromata. The nurse was taking her pulse when Mrs. A. cried out, went through a clonic stage into a tonic one, and remained unconscious. I saw her three-quarters of an hour later when she had had two more fits. She was deeply unconscious, and while I was examining her had another seizure, which was a typical epileptiform one. Dr. F. M. R. Walshe kindly saw her in consultation with me within two hours of the first fit and could find no explanation. Soluble Luminal was given, and after three more slight fits in the night no more occurred, although the patient remained unconscious. After 24 hours I did a lumbar puncture; the fluid was not under pressure, was clear, and chemically and cytologically normal. Within two hours there were signs of returning consciousness. No urine was passed for 36 hours, and only 2 oz. could be drawn off by catheter. This was loaded with albumin, but there were only a few hyaline casts present. There was now enormous anasarca, but the blood-urea was never above 50 mg. per 100 c.cm. The blood pressure was 150/100, which was surprising, for it had never been raised before the first fit. The chest was again full of fluid, which, on Dr. F. G. Chandler's advice, was not aspirated.

The signs of returning consciousness were so encouraging that I once more tried salyrgan, giving 3 c.cm. intramuscularly, and in the following 24 hours she passed 296 oz. of urine! By the time she had passed 100 oz. consciousness had returned. And after three more doses of salyrgan all œdema had gone, the blood pressure was normal, and she felt well. But the temperature still ranged between 99° and 101°, and no cause for this could be discovered. So, on purely empirical grounds, I gave her a series of subcutaneous injections of arsenious acid (rising from 1 mg. to 10 mg. and down again), and her temperature became normal and stayed so.

She returned home in time for Christmas, 1934, still being thin and weak on the legs, and still having an extensor plantar reflex on the right side. Since then she has continued to regain strength, the plantar reflex has become normal, and her temperature has not been above 98·4°. Her blood is normal and one may presume that after having been given up three times she is now cured. But what was the nature of her renal lesion is indeed a mystery.

The case seemed to be worthy of record because one so often tries to encourage relatives by saying "while there is life there is hope," but it is rare to meet a case in which this tentative optimism is justified.

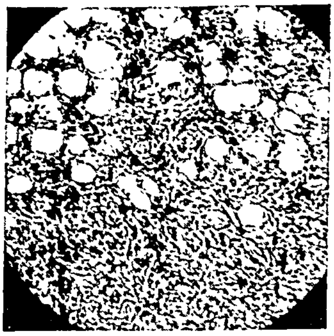
MALIGNANT KELOID FOLLOWING VEIN PUNCTURE

BY M. L. KENIG, M.D. Montpellier

RESIDENT MEDICAL OFFICER, FRENCH HOSPITAL AND DISPENSARY LONDON

IN 1918 the patient, a healthy male aged 44, had some blood withdrawn from a vein in the antecubital fossa. He remembers that afterwards a bruise persisted for "months," and later a scar could be seen and felt at the place where the needle had penetrated the skin. In 1932 a nodule the size of a pea was first noticed. From 1932 to 1935 more growths developed, and as the application of iodine did not disperse the tumours hospital advice was sought.

On examination three nodules about 20 mm. in diameter were found in the anterior bend of the elbow. There was no discoloration of the skin covering them, and when palpated they were found to be attached to the deep tissue and could not be moved freely one from another. Other smaller deep irregularities were felt. On pressure with a glass slide the skin over the larger nodules became cyanosed. Mr. Cecil Burnham, senior surgeon to the French Hospital, diagnosed the condition as malignant, and decided on operation. On Jan. 9th, 1935, he made an incision wide of the tumours and removed them en masse. A considerable number of large vessels arising from the deep fascia supplied this area, and care was taken to remove all the smaller growths which were spreading from the under surface of the main larger masses. The raw surface of the wound was covered with sterile gauze until Jan. 23rd, when a Thiersch graft was done. It is of interest to note that the graft had completely "taken" within five days, and that except for slight œdema distal to the graft the wound had consolidated a fortnight later, allowing full flexion and extension of the elbow-joint.



A field demonstrating the invasion of fatty tissue by the spindle cells. (Low power magnification.)

The tumours were sent to the laboratory for histological examination, and Dr. H. Schwabacher's report was as follows: "The dorsal surface of an elliptical piece of skin 8 by 5 cm. is rendered uneven by circular elevations varying from 2 to 15 mm. in diameter. On the subcutaneous surface these elevations are seen as oval or round nodules, about fifty in number. They are resistant to the knife, their cut surface is glistening, and they are fused together so that they cannot be dissected one from the other without including fatty tissue and fibrous strands. The section shows a mass of spindle cells spreading in all directions and invading the muscle and fatty tissues. There is no attempt at encapsulation. The individual cell has an oval nucleus which takes up almost the entire breadth of the cell. Only a few mitotic figures can be seen, and the blood is retained within the lumen of the vessels of which the endothelium is intact. The growth has probably arisen from the scar tissue of the venepuncture, and on account of the absence of evidence of great activity it may be regarded as a locally malignant keloid."

I wish to express my thanks to Mr. Burnham for permission to publish this case, and to Dr. Schwabacher for the pathological report.

A CASE OF CANNABIS INDICA INTOXICATION

By E. T. Baker-Bates, M.D. Liverp., M.R.C.P. Lond.

ASSISTANT HONORARY PHYSICIAN, ROYAL SOUTHERN HOSPITAL, LIVERPOOL; REGISTRAR AND PATHOLOGIST, LIVERPOOL HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST

Instances of poisoning from Indian hemp grown in England are uncommon; it has been stated [1] indeed that plants grown in this country do not form the active resin and have little or no pharmacological action. The following cases are therefore of toxicological importance.

A young man, having read about Indian hemp in the "Chemistry of Common Life," by J. F. W. Johnston [2] which describes it as "an increaser of pleasure, the exciter of desire, the cementer of friendship, the laughter-mover, and the causer of the reeling gait," separated the hemp seeds from the parrot food and planted them in his garden during June. In September, when the plants were about four or five feet high and flowering, he plucked the leaves and tops, dried and chopped them and made them into cigarettes; these he smoked on several occasions and experienced mild symptoms of cannabis intoxication —e.g., loss of sense of time and space, vivid dreams or hallucinations and subsequent drowsiness.

Incredulous about his experiences, his fiancée, aged 22, smoked—and to some extent inhaled—about two-thirds of a cigarette, made from the top of a fruiting plant. This was at about 10.10 P.M. Soon afterwards she fell asleep and a few minutes later, on being disturbed, she awoke with a start and exhibited apprehension. The eyes were bright, the hands were twitching, and she appeared intoxicated; she asked where she was—probably deceived by hallucinations—but seemed happy. At about 10.25 P.M. she was taken for a short walk, which was interrupted by outbursts of laughter and of affection; her speech became slurred from dryness of the mouth and her gait increasingly unsteady. At 10.30 P.M. she was taken to a doctor and the history explained; he recorded that she was pale, but able to stand and walk although feeling dizzy; she was very excited and talkative and made stiff purposeless movements with her hands; her state was highly emotional, even amorous, towards her companion; at one moment gay, she was next anxious and said she felt "enclosed"; she exaggerated the passage of time and was confused about spatial dimensions; her tongue and mouth felt parched and words were pronounced with difficulty, while sentences lapsed into incoherencies; the eyelids were half closed; the pupils dilated, but reacted to light; the pulse was rapid, but strong.

She was transferred by police ambulance to the casualty department of the Liverpool Stanley Hospital where she arrived at 11 P.M. in a collapsed condition. Her symptoms at that time were loss of power in the legs and inability to stand; dizziness, dryness of the mouth, and palpitation; and lengthened estimation of the passage of time. She believed her condition had lasted many hours and, although fully conscious of her existence, she imagined she was "outside her own body" (a hallucination of dual personality), enclosed in a small space, and surrounded by a mist from which she could not escape. This imaginary mist did not impair her vision for distant objects.

On further examination speech was found to be confused, rambling, and often inarticulate. She was unable to stand steadily or without support, and showed great incoördination in the movements of the hands. There was tachycardia (140 per minute) and also marked inspiratory dyspnœa. No other abnormality was found. Following general treatment for shock the patient recovered in nine hours and there were no sequelæ except severe headache.

These cases are interesting in that they refute the impression that cannabis indica grown in England is devoid of toxic properties and they exhibit the two typical illusions—those of time and space—and the rapid onset following inhalation of the drug of characteristic symptoms which could be divided into three stages—namely, excitation, motor incoördination, and narcosis.

Pharmacologists recognise great variation in the activity of cannabis indica and much difference in the susceptibility of varying races and temperaments to its action. Fatal results are rare. The initial symptoms, which are clearly due to depression of judgment and the critical faculties, are commonly represented by apparent exhilaration of the intellect, associated with—as in normal dreaming—a rapid flow of pleasant and fantastic ideas and illusions resulting in hilarity or demonstrations of affection, and a gross exaggeration of the passage of time as well as an ocular illusion that near objects are at a distance. There may be sexual excitement, but this is dependent on the psychology of the individual. If the action progresses, there will follow sensory impairment and muscular incoördination, and ultimately deep sleep which may be associated with vivid dreams. On awaking there is commonly some lassitude and impairment of mental functions.

Frequent indulgence in cannabis, which is as prevalent as the hashish habit in the East and latterly in Mexico and South America, results in loss of judgment and restraint and is accountable not only for cases where natives "run amok," but also for various types of insanity.

From the medico-legal standpoint this case is interesting, because although the Dangerous Drugs Acts control the purchase of the extract and tincture of cannabis indica, there is no law against the possession of or smoking of the plant. The man could have been proceeded against under the offences against the Persons Act 1861 for giving a drug to another with harmful intent.

The hot summer of 1933 may have been the reason why the seeds grew so well in England. There is a possibility that if the fact that hemp seeds could be grown with ease in England were widely known hemp-smoking might become a national menace. In conclusion I wish to express my gratitude to Prof. Walter Dilling for his interest and advice in this communication.

Children's Hospital, Pendlebury.—The foundation-stone of the Zachary Merton convalescent home, which is to be part of this hospital, has been laid by the Lord Mayor of Manchester. The home will consist of an administrative block with two single-storey wings, each accommodating 20 children.

MEDICAL SOCIETIES

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY

AT a meeting of this society held in the University, Liverpool, on March 22nd, Mr. A. GOUGH, the president, being in the chair, Dr. F. J. BURKE read a paper entitled

"Amniography"

In recent years, he said, it had been found possible to diagnose placenta prævia by means of the X rays. The importance of this discovery was not widely appreciated in spite of the need for improvements in the method of diagnosis. After a brief summary of what had been done by others, Dr. Burke described some of the difficulties and gave the results of 23 cases; in 5 of these X rays showed a placenta prævia. There did not appear to be any gross risk to the mother. Of the 5 neonatal deaths and stillbirths in his series, 4 could be accounted for by natural causes. An injection of uroselectan into the uterus tended to induce labour; he described 27 cases in which it had been used for this purpose. Five abortions were also induced by means of uroselectan, and he discussed the types of cases in which it should prove useful. A large proportion of the drug he had found was excreted by the kidneys.

Dr. C. H. WALSH said that injection of uroselectan into the uterus had the following uses: (1) to show up the fœtus in early pregnancy; (2) to demonstrate the position of the placenta; and (3) to induce abortion or labour. The method was, he added, entirely without risk to the mother and child.—Mr. J. ST. GEORGE WILSON said he had used the method in a few cases but had not been entirely successful because the X ray films were too small.—Prof. MILES PHILLIPS agreed that the method described might be of value in some cases.—Prof. D. DOUGAL asked if the position of the placenta could not be shown by a simple X ray without previous injection of any opaque substance.

Prof. A. LEYLAND ROBINSON and Mr. M. DATNOW described a case of

Vesico-vaginal Fistula

of unknown origin, with a new apparatus for the control of urinary incontinence. The patient was aged 45, a two-para, and had had her last child 15 years previously. She was two years after the menopause and came to the hospital complaining of urinary incontinence of only one month's duration. Examination revealed a large vesico-vaginal fistula about half-way up the anterior vaginal wall. No growth was present. Urinary investigation for tubercle bacilli proved negative and the Wassermann reaction also was negative. Uroselectan injection showed complete absence of function of the right kidney with hydronephrosis on the left side. The left ureter was dilated in its whole length. Operation failed to close the fistula. The speakers demonstrated the apparatus which the patient had found very satisfactory for controlling her urinary incontinence. They had also inserted the instrument in other cases with satisfactory results. It consisted in the main of a ring pessary with a diaphragm to which was vulcanised a rubber catheter whose end was inserted into a bag that was worn on the patient's leg. The instrument has to be removed and cleansed each week.

Miss G. GRIFFITH described a case of

Complete Avulsion of the Uterus

during an attempt at manual removal of the placenta. The patient was delivered by forceps of a stillborn infant. No difficulty was encountered. The prac tioner attempted to express the placenta and th decided to remove it manually because of the excessi bleeding. On removing her hand from the vagi she found to her amazement that it was the ute which she held in her grasp. After admission hospital and treatment for shock, laparotomy w performed and the peritoneum sutured. Miss Griff demonstrated the specimen.

Prof. DOUGAL described a case which was report to the Obstetrical Society and said that very lit force was required to avulse the uterus.—Prof. MI PHILLIPS had collected 36 cases of avulsion, 15 whom had recovered. There was little or even force needed to be used for removing the uterus. these cases there could be no doubt that more or l complete separation of the uterus from the vagi occurred spontaneously. In other cases there w evidence of varying degrees of violence.

Mr. T. N. A. JEFFCOATE described a case of

Hydatidiform Mole

with negative Aschheim-Zondek reaction. He dr attention to the fact that undue enlargement of t uterus was not an invariable accompaniment hydatidiform mole, and his case was an example this. The test carried out with the urine in t patient gave a negative result. This was, he thoug due to the fact that the mole was dead and t chorionic elements inactive.

The PRESIDENT described a case of typical hy tidiform mole in which the test had been negative some unexplained reason. He suggested the pos bility that the urine in some cases of hydatidifo mole contained so much hormone that the test anim did not show any reaction unless the urine w diluted first.—Prof. MILES PHILLIPS said it had be brought to the notice of the society by Prof. Brig that in many cases of hydatidiform mole the uter was smaller than expected.

Cases of specimens were also described at t meeting by Mr. N. L. EDWARDS, Dr. A. A. GEMME Dr. V. J. WOODWARD.

ROYAL ACADEMY OF MEDICINE IN IRELAND

AT a meeting of the section of obstetrics held the Royal College of Physicians on Feb. 8th, t president, Dr. T. M. HEALY, being in the chair, Dr. DAVIDSON, Master of the Rotunda related a case of

Dystocia due to Cyst of the Broad Ligament

Obstructed labour due to ovarian cysts was, he sa comparatively rare and difficulty due to parovari cyst was rarer still. The patient was 34 years age, in her sixth pregnancy, and had had 5 full-te children. Labour commenced at 11 A.M. and t membranes ruptured at 5.30 P.M. She was seen two post-graduates from the hospital who diagnos an ovarian cyst obstructing labour and had her remov to hospital. Shortly after admission Dr. Davids examined her and found her to be in good labou on abdominal palpation the head was presenti and well pushed over to the left side of the pelv brim, showing no attempt to enter the brim. vaginal examination the os was 4 fingers dilated a pushed towards the left lateral fornix; the membran were ruptured and the head could be felt free abo the brim. The right lateral fornix was occupi by a tense cystic swelling the size of a grape-fru which appeared to be fixed to the pelvic wall and could not be dislodged. The uterine vessels could be felt pulsating across the vaginal aspect of the tumour. Pressure on the tumour caused the patient to complain of pain running down her right leg and finally localised in the dorsum of the right foot. The same pain was felt on abdominal palpation and she had noticed it during the latter part of pregnancy, with occasional swelling of the right leg.

It was obvious that vaginal delivery could not take place under the existing conditions. When the abdomen was opened palpation revealed a cystic tumour lying extraperitoneally in the lateral fossa and attached to the lateral and posterior aspects of the pelvic wall. Both ovaries were normal. A lower segment section was performed and a living child was extracted. The incision in the uterus was complicated by very free venous bleeding. After the placenta was removed, and the uterine incision closed, the relationships of the tumour were investigated through the peritoneal incision. The ureter was felt coursing along the superior and lateral aspect of the tumour and the tumour itself was found to be of a cystic character, fairly firmly attached to the floor and the lateral and posterior walls of the pelvis. It would have been possible to have separated it, but it was felt that the amount of hæmorrhage and the difficulties entailed contra-indicated its immediate removal. It was apparently a broad ligament cyst which had extended out from between the layers of the broad ligament. The kidneys were normal.

Dr. F. Doyle asked what would be the right course if such a tumour was found earlier in pregnancy. It was, he thought, always best in such cases to be as conservative as possible.

Dr. O'Donel Browne said the fact of the fixation of the tumour was crucial. If the tumour was fixed, it ruled out the possibility of being able to push it up; if any effort were made at forcible delivery, the tumour might prove to be a dermoid and burst. It was difficult to know what a country practitioner could do in a similar case. In the case of a patient with threatened rupture, the child alive, and the cervix fully dilated, he himself would have done a version. Such tumours used to be drained through the rectum; and according to old text-books this treatment seemed to do well.

Dr. R. V. Dowse referred to a case in which tumour complicated pregnancy. The patient, a primipara, was six months pregnant. She had a fibroid so sensitive that she could not bear her abdomen touched. It was removed and the patient went to term.

Dr. Davidson in reply said that the patient had her last child three years previously; she had had no difficulty with previous confinements. If the cyst was present at all three years previously, it must have been very small; in the early stage of pregnancy it would probably not have been big enough to be felt. In one case of fibroids in pregnancy he had operated when the patient was about five months pregnant and removed large interstitial fibroids. There was severe haemorrhage, the cavity was only closed with much difficulty, and the patient miscarried. In another case he had removed subperitoneal fibroids and the patient did well. If fibroids were present in the upper part of the uterus and were interstitial or non-pedunculated he thought they should be left alone. In other cases they should only, he thought, be touched if their removal would save the patient from a Cæsarean section. In the present case he did not think that any type of vaginal delivery would have been satisfactory; the cyst was very tense, and any attempt at vaginal delivery would almost certainly have ruptured it. He hoped in about six months' time to be able to remove the tumour.

At a meeting of the section held on March 8th Dr. W. R. Collis read a paper on

Premature Infants and their Management

The difficulty of maintaining the body temperature of these children had, he said, been largely overcome at the Rotunda by the administration of thyroid extract. It was very difficult to keep the temperature up by external means only. The babies were nursed in electrically heated cots, the nursery itself being kept at ordinary room temperature as it was found that high temperatures interfered with the efficiency of the nursing staff. Weight curves showed that the babies on thyroid extract compared well with the control babies treated without it.

The President said that most obstetricians realised they had not been doing enough for babies when they were very small. Dr. Collis had mentioned that nurses did not even take the temperatures of babies when they were premature; they concentrated all their attention on the mothers. The results following the administration of thyroid were impressive and future results might be even better. He deprecated wrapping up the babies in gamgee tissue; it did not keep them particularly warm, and warmth was essential.

Dr. Davidson confirmed the results gained by the administration of thyroid extract. One of the most important changes which had recently taken place in the Rotunda Hospital was the appointment of a staff nurse for the nursery.

Dr. Bethel Solomons said that nursing was the most important part of treatment in prematurity; he had always taught that heat and fluids were the keynotes of success. Thyroid extract seemed to be an excellent adjunct in producing heat. Babies of three pounds and upwards survived with good treatment. In Holland the urine of pregnant women was being used in the treatment of premature infants as the readiest way of obtaining hormones.

Dr. Dorothy Price said that Dr. Collis had revolutionised in Dublin the treatment of premature babies. It was a great advantage to the pædiatrician to see the babies in the Rotunda immediately after they were born, before they had had a chance of picking up any germs.

Dr. Colman Saunders said the chief difficulty about premature babies was their feeding. The gastric mortality was very high. Thyroid, he thought, probably acted by increasing the gastric and intestinal resistance. It was however very difficult to give enough to be really effective. The temperature should be taken from the moment the baby was born; it might be too late when it was found that the temperature was going down. He thought any baby under five pounds when born should be treated as premature.

Dr. Collis in replying said he did not like gamgee tissue for these babies; it was much better after they had been impregnated with oil to wrap them in a woolly shawl. He quite agreed with Dr. Davidson that the chief credit for the good work in the nursery was due to the staff nurse. These babies were always very anæmic, and many of them would die unless they were very well looked after. It was often extremely difficult to get them to take any food at all; it was often necessary to put it in with a tube. Carefully done this would not start bad diarrhœa. In Germany there was a regular trade in breast [illegible]

REVIEWS AND NOTICES OF BOOKS

Respiration

New edition. By J. S. HALDANE, C.H., M.D., F.R.S., Fellow of New College, Oxford; Hon. Professor of Birmingham University; and J. G. PRIESTLEY, M.C., D.M., Reader in Clinical Physiology in the University of Oxford Oxford: Clarendon Press; London: Humphrey Milford. 1935. Pp. 493. 30*s*.

THIS new edition of Prof. Haldane's well-known work on respiration is a welcome addition to physiological literature. The subject is treated exhaustively from beginning to end in all its bearings. An historical account is given of the development of ideas on the control of breathing and the respiratory function of the blood, while the greater part of the book is devoted to consideration of respiration in its widest sense in relation to the economy of the whole organism. The sections on the effects of high and low atmospheric pressures make fascinating as well as instructive reading, and are beautifully illustrated. From a practical point of view the main message of the book hinges round the problem of anoxæmia; indeed, the authors say: "If there were only one clinical lesson derived from a perusal of this book, it is to be hoped it would be that anoxæmia is a very serious condition, the continuance of which ought to be prevented if at all possible." Many of the apparently specific effects of carbon monoxide, for instance, have been shown to be really due to the effects on the tissues of prolonged—sometimes unnecessarily prolonged—partial deprivation of oxygen. The last chapter, on air of abnormal composition, treats of a variety of subjects, including ventilation, ordinary lighting gas, air in mines, air containing particulate matter, and air in wells and tunnels and ships.

From the scientific point of view the approach to the subject is epitomised in this sentence, taken from the preface: "Respiration is thus only an aspect of the coördinated and maintained phenomena which we call life." In working out the details of respiratory processes, the authors never lose sight of the organism as a whole, and they regard the integration and coördination of such details as a fundamental conception which must be accepted and which may be used for purposes of prediction. There is no doubt that the philosophical outlook which Prof. Haldane has championed for so many years is implicitly, if not explicitly, becoming more and more acceptable to physiologists. Perhaps most of them would subscribe to the idea that even if the body could be completely presented as a series of physico-chemical mechanisms, their coördination and maintenance would still represent a peculiar and characteristic type of activity which we could only describe by a unifying term such as life. This is probably an understatement of Prof. Haldane's case, but it is clear that we must at some stage take for granted the existence of a unifying factor. Too much importance is often attached to the fact that Prof. Haldane's belief in oxygen secretion by the lungs is not accepted by several other workers. The question of oxygen secretion is one of evidence, and the most that can be said here is that the evidence is conflicting, and that in this book very cogent arguments have been adduced in support of the contention that it does occur; if this contention should be proved incorrect, however, the main thesis of the work would not be invalidated. Apart from this chapter, which deals a little one-sidedly with a controversial point, the book is authoritative in every respect, and it is safe to say that no other authors could have combined so well the theoretical and practical aspects of their most important subject.

Medicine

Essentials for Practitioners and Students. Second edition. By G. E. BEAUMONT, D.M., F.R.C.P., Physician with charge of Out-patients, Middlesex Hospital. London: J. and A. Churchill Ltd. 1934. Pp. 746. 21*s*.

THE bold venture of producing a small text-book of medicine to compete with so many bigger rivals has achieved a deserved success. It is indeed the compact nature of this work which is partly at least responsible for its popularity, for it includes all the essentials of medicine in small bulk. Moreover, its price is very reasonable, and it is well illustrated and beautifully printed on excellent paper. To read a book containing such a wealth of compressed information is not easy work, but this is a defect which can hardly be avoided. A difficult subject like nephritis, for example, cannot be clearly expounded in a short essay; the student is likely to feel almost as puzzled after reading this section as before, and even the experienced practitioner may not feel quite sure of his ability to differentiate the types in which a raised blood-urea is to be expected, or in which urea should be ordered as a diuretic. Similarly the classification of jaundice may well alarm those meeting it for the first time. These are however criticisms which are equally applicable to larger works, and it is only because conciseness and simplicity must be the two important standards in judging the smaller text-book of medicine that they are mentioned here. Dr. Beaumont has combined the new and the old in medicine and managed to shake off much that needed eliminating. He shows common sense everywhere, and his emphasis on clinical aspects of medicine is welcome in a text-book of this sort. In this edition a number of minor alterations and additions have been made, and the book is now wonderfully up to date and complete for its size.

Practitioner's Library of Medicine and Surgery

Vol. VII. *Pediatrics.* Associate editor: DANIEL C. DARROW, B.A., M.D., Assistant Professor of Pediatrics, Yale University Medical School. London: D. Appleton Century Co. 1935. Pp. 1211. 50*s*. per volume. (Volumes not sold separately).

THE presentation of an up-to-date and inclusive exposition of the practice of pædiatrics as part of a system of medicine and surgery involves a certain amount of overlapping with other sections of the general work. Many infective diseases affect adults in much the same manner as they do children, and for this reason the editors have stressed rather the nutritional factors of disease in childhood, and such conditions as tuberculosis in which there may be considerable differences in kind between the adult and childhood type of infection.

The editor courageously prefaces the volume with the statement that the "great morass of speculative matter has been 'debunked'; opinion has been superseded by established facts." The process of debunking, however, has been put into 34 different hands, and their efforts are by no means equally successful. Indeed, we suspect that some of them have found it very much like debunking the hydra—no sooner is one head amputated than another takes its place. But the whole subject has been approached in a spirit free from traditional shibboleths, and the result is a work which is thoroughly alive. Pædiatricians in this country will welcome a symposium giving the views, in many places, of the younger Americans of many different schools, and there is no doubt that even as a work of reference, several of the sections could hardly be bettered. Unfortunately, there is occasional manifestation of a tendency to a wordiness that seems due not so much to inaccurate thought as to inadequate powers of expression. This depreciates the value of the book from the point of view of the busy practitioner, although there is a wealth of information provided for those who are prepared to sift it. The doctor in this country may be somewhat disappointed to find how little space is devoted to the use of drugs, but he will find more than adequate compensation in the description of the rationale and technique of a great variety of other methods of treatment. A curious omission is that of any mention of continuous intravenous therapy in gastro-enteritis, a method which, though of limited application, has surely justified its use in selected cases.

The production of the volume reaches a high level. The illustrations are for the most part happily chosen, although there are too many photographs of brain sections for a work essentially clinical in character. Most of the chapters are profusely documented. The project as a whole is such an ambitious one that it is high praise to say that in the main it has achieved success.

Diseases Peculiar to Civilised Man

Clinical Management and Surgical Treatment. By GEORGE CRILE, M.D. Edited by AMY ROWLAND. New York: The Macmillan Company. 1934. Pp. 427. 21*s*.

THE diseases peculiar to civilised man, according to Dr. Crile, are hyperthyroidism, neuro-circulatory asthenia (the D.A.H. of war-time medicine), peptic ulcer, and diabetes. They are not due to infection, climate, food, or muscular work; therefore their basis must be in man's racial history. In the zoological past certain animals seem to have become extinct because the overdevelopment of one organ handicapped them hopelessly in the struggle for existence; thus the sauropod dinosaurs died of gigantism, and the weight of the antlers of the Irish elk bore him down to extinction. This phenomenon of continuing variation in a fixed direction, even when that direction is racially disadvantageous, may also be seen in the human species. Man's brain and thyroid are developing, while his special senses, teeth, muscles, and digestive organs are regressing from comparative disuse. With the brain and the thyroid are associated the sympathetic nervous system and the adrenals to form a kinetic system, which by initiating and transforming energy drives the rest of the body—and much of the outside world as well. That system has lifted man into his pre-eminence in nature, and now threatens by its restless hyperactivity and unbalanced overdevelopment to drive him to destruction. The signs of his yielding are the four disorders named above, with one or two less common ones like Raynaud's disease.

Such, in brief, is the thesis developed by Dr. Crile in the first part of this book. His thought is exuberant, his style vivid and clear; and he is quite uncritical. The next section argues that treatment of the "hyperkinetic" disorders should aim at diminishing the influence of the brain-thyroid-sympathetic-adrenal system over the rest of the body, and that this can be done by denervating the adrenal glands. The technique of the operation is described. There follows a series of case reports occupying more than half the book, purporting to show that the operation produced improvement or cure in most of the three hundred odd cases in which it was performed at the Crile clinic; but if the cases have been assessed with the same undiscriminating enthusiasm as characterised the opening argument, we should prefer to look to more critical sources for practical confirmation. The book is worth reading for the stimulation which some of the ideas and arguments will certainly provoke, but as a guide to treatment it scarcely inspires confidence.

Ideal Health

Third edition. By ALEXANDER BRYCE, M.D., C.M., D.P.H. Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall Ltd. 1935. Pp. 340. 5*s*.

THIS book deals with food, drink, work, exercise, rest, air, cleanliness, clothing, regularity and moderation, the influence of the mind on the body, and eugenics. Stress is laid upon the physiological basis of the practice of hygiene, whether personal or corporate, and the views put forward are mostly orthodox. In this edition the material has been brought up to date, although the discussion of ventilation is hardly in accord with modern thought. In so far as it is possible for one writer to cover the very wide field of sciences upon which the book touches, the work has been well done. Discussions on such matters as baldness, as to the prevention of which the author has definite views which can hardly be substantiated, and prescriptions of remedies and prophylactics might have been omitted. Many scientific works are mentioned but no accurate references are given; phrases like "recently" or "a few years ago" are not helpful to any student who might wish to consult the writers quoted.

This book is intended for all who are interested in the preservation of health and is therefore written in simple language, but the author hopes that it may be useful to teachers of personal hygiene and students of medicine.

Spectrum Analysis

Clinical and Pathological Applications. By Dr. WALTHER GERLACH and Dr. WERNER GERLACH. London: Adam Hilger Ltd. 1934. Pp. 143. 14*s*. 6*d*.

THE application of spectrographic methods of analysis to biological problems has been delayed because of unsuitable methods of exciting luminosity. Using the so-called high-frequency method, in which high-frequency oscillations in one circuit are transferred by induction to a second oscillatory circuit containing the spark gap used for the analysis, the authors have succeeded in obtaining an insight into the distribution of metals in organic samples. The great advantage of this method is that the most important requirement of spectrum analysis, the avoidance as far as possible of any chemical reagents, is fulfilled. The laborious task of extracting minute amounts of metals by chemical means, with the constant danger of introducing extraneous impurities, is thus avoided. The high sensitivity of spectroscopic analysis renders possible the examination of a piece of tissue, fraction by fraction, so that not only is the presence of the metal proved, but its distribution throughout the organ may be visualised. Using the "method of homologous pairs of lines," in which known quantities of a second metal are added to the tissue for comparative purposes, a quantitative method has been elaborated. The authors are so confident of their technique that the histochemical and spectrographic methods of other workers are discussed and their limitations and fallacies laid bare.

The greater part of the work deals with the application of spectrum analysis. This section is not confined to clinical and pathological applications, as the title of the book suggests, but includes mineralogy and geochemistry. The authors suggest that the study of the distribution in the body of heavy metals administered in therapeutic doses should prove interesting, since in the case of gold they found a certain specificity of the metal for tuberculous tissue.

Tuberculosis in the Child and the Adult

By FRANCIS MARION POTTENGER, A.M., M.D., F.A.C.P., Clinical Professor of Medicine (Department of Chest), University of Southern California, the School of Medicine. London: Henry Kimpton. 1934. Pp. 611. 36*s.*

"Believing that it is the duty of specialists now and then to give back to the general profession an epitome of the knowledge that they have acquired," Dr. Pottenger set himself the task of concentrating the results of many years of study and practice within the limits of a single volume, intended primarily for the use of students and young practitioners. Special attention has been given to what the author describes as major problems in the study of tuberculosis, to childhood infection, to the reactions of the body towards infection, and the part that immunity reactions play in diagnosis; but every aspect of pulmonary tuberculosis has been carefully considered in a work which represents a survey of the whole field. Dr. Pottenger is no apologist for the use of classical methods in clinical examination, but though he rightly condemns those whose zeal for scientific methods of investigation leads them to neglect the more important study of the patient, he attaches a significance to the finer details of physical examination which to the modern student may seem somewhat exaggerated. His claim that the practice of palpation if diligently pursued will result in such an exquisite sensitiveness of finger that even the large bronchi and blood-vessels and the hilar densities can be detected when in their normal conditions might create a feeling of despair in the student who compares the results of his most careful clinical examinations with the shadows of pathological conditions as revealed by radiograms. It is difficult to credit the statement that by light-touch palpation it is possible to feel deep within the thorax; and feel so accurately as to be able to translate the perceived data, not only in terms of greater or lesser density, but also into terms of clinical pathology with remarkable precision. Even if such skill were possible of attainment, the average student could not hope to achieve it in the time at his disposal, or the practitioner to employ it in his daily practice.

The chapters devoted to therapy are excellent, and the student will find here all that he requires for the treatment of the various forms of the disease and of its symptoms and complications. The sections dealing with collapse therapy will form a useful guide to those who are perplexed by the optimistic claims proffered by some and the slighting references made by others to the more active forms of treatment.

The work is well illustrated by figures and skiagrams; clinical interest is maintained by numerous descriptions of illustrative cases, and the bibliography is more than sufficient.

We commend this book to the notice of British readers.

Précis d'histologie

La cellule, les tissus, les organes. By A. BRANCA and J. VERNE, Professeurs à la Faculté de Médecine de Paris. Paris: Masson et Cie. 1934. Pp. 635. Fr.50.

THE labour of producing this sixth edition has been borne by Prof. Verne. The form of the previous edition has been retained and, without adding appreciably to bulk, the various sections have been revised and brought up to date. The work aims at providing what is necessary to the student for his examination in histology and a means of revision for the post-graduate. The result is a competent and sufficiently comprehensive text-book arranged on conventional lines. It is profusely illustrated with drawings in black and white, many of which are far too small, while others are somewhat smudgy and uninspiring. It enjoys the distinction, rare in French books, of being strongly bound in cloth, but this advantage is offset by the inclusion, at the end of the volume, of 48 pages of publishers' advertisements.

JOURNALS

IL BAGLIVI No. 1, January–February, 1935, issued bi-monthly. Annual subscription: 50 *lire* in Italy, 100 *lire* abroad. G. C. Sansoni, Florence.—This is a new Italian journal dealing with all departments of medicine and appears under the direction of Dr. Gaetano Gentile. It is admirably printed. Four sound clinical essays are followed by a group of brief reviews, while the last third of the journal is taken up with abstracts from contemporary literature. These are interesting, and where they can be tested appear to be carefully done, but one may be permitted to guess that the staff employed on the work are not familiar with the English language. A foreword brings to modern notice an Italian savant whose name does not occur in medical literature with as much frequency as might be expected, either from his ancient fame or his accomplishments. The journal is named after him.

Giorgio Baglivi was born in 1668 and received his medical education at Rome, where he came into close contact with Malpighi, whose teachings he profited by and whose autopsy he performed. He succeeded Lancisi in the chair of anatomy in 1696 or 1697, and shortly afterwards published *De Praxi Medicá*, described in the first English translation as "the practice of physick reduced to the ancient way of observations; containing a just parallel between the wisdom and experience of the ancients and the hypotheses of modern physicians." The work was translated also into German and French at different dates, and procured for Baglivi a wide reputation and election to the Royal Society. He died in 1707, being only in his 39th year.

THE centenary volume of St. Mark's Hospital, which was reviewed last week (THE LANCET, March 30th, p. 756), is published by Messrs. H. K. Lewis and Co., Ltd., London, price 30s.

REHABILITATION AFTER INJURY

Dr. H. H. KESSLER, who is head of the Rehabilitation Commission at Newark, New Jersey, told the Royal Society of Medicine on Jan. 15th, that after attending a rehabilitation centre most disabled workers were able to go back to the work they had done before. He made an exception, of course, for major amputations. A rehabilitation service was, he said, available in 44 of the American States; all of them provided vocational training for the civilian disabled. The State of New Jersey was unique in offering surgical and medical rehabilitation as part and parcel of the workmen's compensation unit; it was supported out of the rates and taxes at a cost of about 50,000 dollars a year. In this unit an assessment of disability was made by the State physician and the referee put the stamp of legal approval upon it. The county court method of adjudicating claims had been tried in the State; it had proved inadequate and was given up. Dr. KESSLER's visit to this country was of necessity a brief one, but he brought with him a film giving a vivid picture of the rehabilitation work done in New Jersey, and this film has been shown several times since he left, including a demonstration last week at Bush House to a select audience of people especially interested in physical disablement, including orthopædic surgeons, representatives of insurance companies and trade-unions, and Mr. GEOFFREY PETO who has special parliamentary experience.

It is a curious thing that there should be in the home counties no training centre for adult cripples, and this is the more remarkable as it was the work of the Lord Roberts memorial workshops which suggested the idea to Dr. KESSLER. There is actually no place where crippled persons whose disability precludes them from being absorbed into industry in the normal way can become fitted to do so by suitable training. There are of course places such as Enham Colony at the service of the war cripple, and it was, we believe, the design of the promoters of Enham to put its facilities at the disposal of civilian industrial cripples when its primary object was achieved. The omission is however now being made good to some extent at the Cripples' Training College at Leatherhead Court, the scheme for which was launched at a Mansion House meeting in March, 1934, and which is to be formally opened in June next. Here the primary object is not vocational training. What the trainees are offered is fundamental practice in electro-mechanical technique as carried out under industrial conditions, concurrently with the assembly and manufacture of articles related thereto on a commercial basis; thus they can learn to adapt themselves to the physical limitations imposed on them by their disablements. At present a charge of 35 shillings per week is being made, but it is hoped to reduce this figure after the first year's running.

The object of Leatherhead Court, as of the rehabilitation centres in the States, is to get the insured man back to his work as soon as possible. How little this is now the case was brought out two years ago at the Liverpool Medical Institution,[2] when Dr. H. E. MOORE, surgeon to the L.M.S. Railway, produced evidence showing that many railway men who had met with accidents might have returned to their former occupations after brief periods of time if their treatment had been adequate. His figures showed long periods of incapacity amongst men whose active treatment had ceased before they were fully restored, and it was pointed out in the discussion that attempts to curtail the unemployable period, or to reduce ultimate disability by coöperation, were met with the reply from the employer "We are insured" and with the reply from the insurance company "We are covered." That is unfortunately one effect of the Workmen's Compensation Acts as at present administered in this country, and everyone present at the Bush House meeting agreed that this was the case. As the B.M.A. Committee on Fractures stated, our compensation Acts, although humane and beneficial in many respects, contain no provision for rehabilitation after injury, and have in many cases played a powerful part in prolonging the injured man's disability. The provision of light work for the disabled or convalescent man presents almost insuperable obstacles. The man himself is often afraid to take up work that might prove too much for him, and it is no wonder that to-day, with so much unemployment, there is a tendency to nurse invalidity as an alternative means of subsistence. An actual incitement to the prolongation of disability is provided in the lump sum form of compensation. The B.M.A. Committee had before them evidence that solicitors' touts wait on accident cases to promote profitable litigation, and the improvement is often amazing in the condition of a man, who has been long kept wondering what amount of compensation he would get, when the lump sum is paid. These crippled men are apt to drag on in misery partly because of the variety of agencies from which they can obtain certificates of disability, and partly because, as things are, our insurance companies are interested primarily in compensation and not in rehabilitation. There are some five Government departments concerned and since everybody's business is nobody's business, there is no initiative towards the great national scheme required to re-administer the workmen's compensation laws in the interest of speedy recovery. Employers fear that the man who has had one accident is more likely to have another, and they have been recently intimidated by a decision that an employee who comes to them with the results of a previous accident and has another will make them liable for both. It is in the interests of all parties to reconsider the present state of affairs

if only on the ground of economy, for it is admitted that in this country 37 per cent. of the premiums disappear in administration, whereas in New Jersey 5 per cent. is sufficient to run the scheme. We wish well to the Leatherhead scheme and trust that it will serve not only as an object-lesson but as a stimulus to general inquiry.

THE METABOLISM OF VIRUSES

By the application of new techniques and the refinement of old ones the viruses are in many respects being brought into line with other forms of organised life. The larger viruses such as vaccinia, ectromelia, or psittacosis, which are big enough to contain between five and ten thousand protein molecules, appear to be more nearly related to living than to non-living systems. It is still difficult to conceive of the mode of life and pathogenic action of the really small viruses such as foot-and-mouth disease, which has a diameter only about four times that of serum albumin. In this search for more precise knowledge about the viruses, M. Schlesinger[1] and H. Schüler[2] studying the chemical composition and metabolism of one of the larger bacteriophages, have obtained results of great interest. They have grown the phage WLL on a strain of *B. coli* No. 14 which itself was growing on a synthetic lactate phosphate medium. The phage was grown for 48 hours, during which time no visible lysis appeared. The bacteria were then filtered off through paper and the filtrate was concentrated by passage through a collodion membrane. The phage remained on the membrane and could be recovered quantitatively. The concentrated suspension was then centrifuged for three minutes at 15,000 revolutions per minute and the supernatant fluid taken and centrifuged again for half an hour at the same pace with 1½ c.cm. per tube. The second sediment was drained, washed with distilled water, and used as the phage preparation. Rabbits injected with such preparations gave no serum agglutinins for the organism on which the phage had been grown, but they did produce antilytic antibodies. The activity of such preparations was tested on *B. coli* No. 88. Schlesinger has investigated the chemical composition of the phage. The elementary analysis gave C 42 per cent., H 6·4 per cent., N 13·2 per cent., P 3·7 per cent.; this roughly corresponds to the composition of a nucleo-protein. Washed centrifuged phage preparations gave positive Millons and biuret reactions, but a negative Molisch test, indicating the absence of carbohydrate. The activity of the preparations may be judged by the fact that 1·0 mg. dry weight of washed centrifuged phage corresponded to $2{\cdot}3 \times 10^{12}$ active phage particles.

Schüler has used the methods elaborated by Schlesinger to investigate the metabolism and enzymes of this coli phage. In most of the experiments 1·0 mg. dry weight of phage was used, but for the experiments on respiration and fermentation up to 17·5 mg. were obtained. Schüler found, using the delicate manometric method of Warburg, that the oxygen uptake and the carbon dioxide productions of even such large amounts of phage were well below the experimental error. If dead bacteria were added to the medium the result was not affected. Nor did phage in amounts not causing visible lysis produce any change in the oxygen consumption of living susceptible coli. Schüler then investigated the hydrolytic enzymes, trypsin, papain, lipase, amylase, maltase, nucleosidase, urease, arginase, and phosphatase. Of all these, phosphatase was the only one found to be present in the phage suspension. This phosphatase hydrolyses hexose diphosphate, nucleic acid, hexose monophosphate, and glycerophosphate. The enzyme seems to have the same general characteristics as phosphatases from tissues and bacteria. The pH optimum is pH 8·5 and the action is inhibited by inorganic phosphate, the inhibition being greater at low substrate concentrations than at higher. Unlike tissue phosphatases the enzyme is not inhibited by fluoride, which does inhibit lysis of bacteria by phage. Schüler found that well-washed phage deposit did not hydrolyse organic phosphates, but that the addition of the supernatant washings restored the hydrolytic power. He therefore postulates a co-enzyme. The reasons for considering that the enzyme is a constituent of phage itself rather than a fragment of the bacteria of the same size as, or adsorbed on to, phage are (1) that a culture of the *B. coli* contains only a very weak phosphatase, and (2) that the amount of enzyme runs roughly parallel to the number of phage particles present. One mg. wet weight of phage hydrolyses 500–1000 γ P_2O_5 per hour at 37° C. and pH 8·5 with 1·0 per cent. hexose diphosphate as substrate. Concentrated bacterial filtrates show only very slight phosphatase action. Since no visible lysis took place during the growth of the ofphage the author concludes that it is unlikely that the phosphatase in the sediment is an internal enzyme of the bacterium which manifests activity only after the disruption of the organism. It is unfortunate that he has not included in his controls the phosphatase activity of the sediment obtained from *B. coli* No. 14 after lysis by something other than phage. The quantitative relationship between the enzyme activity and the number of active phage particles present make it more probable that the enzyme is in fact a constituent of the phage itself; but this does not exclude the possibility that the parallelism between phosphatase activity and the amount of phage present is due to a quantitative adsorption of an intracellular bacterial phosphatase on to the phage particles.

This work is one of the first published accounts of a study of the metabolism of an organism in the submicroscopic class similar to the viruses. A less limited though still small range of enzyme activity was found by B. E. Holmes and A. Pirie[3][4] using the organisms of bovine pleuro-pneumonia and agalactia. In both these organisms only one strong dehydrogenase, that for lactate, could be demonstrated. Centrifuged organisms differed from phage in that they had a measurable respiration in the presence of lactate, and in the case of pleuro-pneumonia a fermentation of glucose and other sugars was well known to take place. The viability of the organisms ran parallel with the enzyme activity, and such treatments as exposure to methylene-blue and light which destroyed the one invariably destroyed the other. It is interesting to speculate on the part played by the phosphatase in the lysis of the bacterium and the growth of the phage. F. M. BURNET[5] has shown that one phage is adsorbed by the specific flocculable substance of the susceptible organism and that after adsorption it can no longer lyse fresh susceptible bacteria. In addition, susceptibility to phage among coliform organisms is related to antigenic structure. It may be that the breakdown of the specific flocculable substances is an essential part of the lysis of a bacterium, and that the phage phosphatase helps to bring this about. It would be interesting to know if the phage used by BURNET contains phosphatase and, if so, what effect the addition of specific flocculable substance had on its activity.

The continuation of SCHÜLER's work should bring interesting results. BURNET and W. J. ELFORD have shown that bacteriophages are of many different sizes, and the next step will be to discover how widespread among them is the phosphatase and how far the enzyme activity is correlated with the power to effect lysis. The new methods of attack given by the high speed centrifuge and carefully graded membranes hold out hopes that the way is now open for a vigorous attack on the problem of the way in which viruses obtain the energy necessary for growth.

ST. DUNSTAN'S

IT is exactly 20 years since the late Sir ARTHUR PEARSON began his work for war-blinded soldiers, sailors, and airmen at a house in the Outer Circle of Regent's Park, whose name is now almost a synonym for the care of the blind. Nearly 2000 blinded men and their families are still under the care of St. Dunstan's, and it is distressing to learn that even at this late date there are new admissions. The nineteenth annual report informs us that 19 new cases were admitted during the year, 5 of whom were blinded by the delayed effects of gas poisoning. The house in Regent's Park is no longer the heart of the organisation, and for that reason, perhaps, there is a chance of St. Dunstan's dropping a little out of the public eye. Any falling-off in support would be a disaster, for the average age of the men is 45 and the youngest is only 33. The administrative headquarters are housed in a building, originally a group of workshops, in the Inner Circle of Regent's Park, and the sales department for articles made by St. Dunstan's men is in Kentish Town. But the training centre is now to be found in the large convalescent and holiday home at Brighton, the gift of the Federation of Grocers' Associations of Great Britain. Here the beginners learn their new occupations and the old patients return for refresher courses or for holidays. The matron, who knows every one of the 2000 personally, is hostess to this large floating population. In one part of the building are wards for totally disabled blinded men who will require institutional care for the rest of their lives.

Most of the old patients of St. Dunstan's are now out in the world earning their living. Their occupations range from shopkeeping and basket-making to poultry farming, boot-making, and carpentry. The St. Dunstan's roll also includes a chartered accountant, a professor of languages, three clergymen, a barrister, a solicitor, and the director of an engineering firm. One keeps a road house. In moments of difficulty old patients find in St. Dunstan's an adviser, encyclopædia, and repair works rolled into one. Medical advice is available for those who are ill; legal advice for those who are in difficulties about National Health Insurance or a disputed right-of-way; financial troubles may be overcome by a judicious grant. Each man has a Braille watch, a wireless set, and a typewriter, all kept in repair by St. Dunstan's. The recreations of blinded men are not as limited as outsiders are apt to think. Many are fond of swimming, and others find the proper competitive flavour in walking matches. Rowing and physical jerks are available for Londoners, and at Brighton some enjoy practice in kicking at goal, which seems to show how deep the passion for Association football goes among British people. Some are keen gardeners. Cards and dominoes are usual pastimes, and the St. Dunstan's Band has even been broadcast in the National programme. Probably the most remarkable achievement of a remarkable organisation is that of maintaining the spirit of good fellowship which prevailed during the war into the carping times of peace.

◆

THE PRE-SCHOOL CHILD

IN opening, from the chair, a discussion at the annual meeting of the National Baby Week Council on March 27th, Dr. G. F. Still said there was need for some better term than "pre-school" child to define the child between the ages of 2 and 5 years. An infant of 6 months old was in some sense a pre-school child, and at 5 years some children had already been attending school for two years. Local authorities did not lack powers to care for pre-school children; the point at issue was how far those powers were being exercised. It was, no doubt, more difficult to provide for their welfare than for that of the school-children, and yet the years from 2 to 5 were fraught with the gravest influences on the child's well-being, influences related not only to physical but even more closely to mental and moral health. He had a profound belief in the value of day nurseries and nursery schools as places where children at a plastic age unconsciously learned order and discipline. Certainly the pre-school age was an age of frailty; the actual risk to life was greater in the three years of pre-school life than in the subsequent school years. In some districts the number of deaths occurring in children between 2 and 5 years of age had been actually greater than in the whole ten years from 5 to 15. He noted the high prevalence of tuberculosis, of respiratory diseases, and specific fevers during the first five years of life. Some of these factors were being combated, and against one of the worst the use of dried and pasteurised milk was a powerful preventive. If a larger supply of milk was to be made available for these children, it should be in the form of pasteurised milk.

ANNOTATIONS

THE INCIDENCE OF TUBERCULOSIS AMONG STUDENTS

THE example set by America and Germany in the matter of large-scale systematic medical examinations of students is being followed by several other countries. Spain and Denmark are among the latest converts to this system. Prof. L. Sayé[1] of Barcelona has recently given an account of such examinations, which were introduced as a compulsory measure at the end of 1933 with the object of discovering tuberculosis in an early stage. Since then 584 male and 53 female students have been examined, and of the 33 found to be tuberculous, as many as 26 had been ignorant of their disease. The comparison made in the course of these examinations between radioscopy and radiography was definitely unfavourable to the former, which in several cases had failed to indicate lesions demonstrable by radiography. When Prof. Sayé's observations were discussed by the French Academy of Medicine, the consensus of opinion was emphatically on the side of radiography. Prof. Bezançon and Prof. Sergent refused to be impressed by unsupported radiological findings and insisted on the balanced judgment which depends on a careful marshalling of all the evidence, including the results of clinical examination. In Denmark, Dr. J. Holm[2] has conducted tuberculin surveys of students with Mantoux's test pushed to 1 mg. of tuberculin. His examination of several hundred medical students showed that the percentage of positive reactions among them rose from 70 per cent. at the commencement of their studies to 98 per cent. towards their close. This rise in the proportion of reactors was not so great in the other faculties, and the deduction that the work of the medical student is more favourable to the development of tuberculosis than that of the other students seems to be justified. Dr. Holm concludes from his investigations that, while only 2 per cent. of all the students in Copenhagen suffer at the present time from active tuberculosis, 10 per cent. of the senior medical students have an active infection.

DIPHTHERITIC PARALYSIS

PARALYSIS of the eighth cranial nerve in diphtheria is rare. Kourilsky, Baruk, and Aubry[3] recently reported to the Paris hospitals medical society a case with bilateral vestibular signs. The mild primary angina had not been treated. They attributed the successful outcome to serotherapy instituted after the paralysis was established. This report stimulated other observers to record another such case; it also provoked renewed discussion on the value of antitoxin in the treatment of diphtheritic paralyses in general. A month later Marchal, Soulié, and Grupper[4] described a case of diphtheritic polyneuritis with involvement of the right auditory nerve. Antitoxin alone failed to affect the condition. Inspired by the technique employed in tetanus, they combined serum treatment with general anæsthesia, and noticed rapid improvement. And at the same meeting of the society Duvoir, Pollet, Kreis, and Greene[5] reported a similar case which had, for a time, been under their care and with which they had lost touch. It transpired that both sets of observers had been reporting the same case. From the two accounts a complete record is available. Fortified by Kourilsky's success, M. J. Comby,[6] an old advocate of serotherapy for paralysis, reiterated his belief in its value and included in his communication the recorded successes. G. Ruelle,[7] on the other hand, is convinced of the futility of the method, and finds support for his scepticism (1) in the impossibility of evaluating treatment on clinical evidence alone, because of the tendency to spontaneous recovery; (2) in Roux's dictum that the action of antitoxin is like that of water in a fire—it prevents spread but does not repair damage; (3) in experimental work rendered possible by the new method devised at the Pasteur Institute by Ramon, Debré, and Uhry[8] of producing diphtheritic paralysis in animals with modified toxin. Using their technique Ruelle[5] investigated various methods of treatment employed in the human subject. He concludes, as did the Pasteur Institute workers, that antitoxin has no curative action on paralyses; nor has toxoid, anæsthesia, urotropine, sodium salicylate, potassium iodide or the oleate, oleo-ricinate or taurocholate of sodium. In a further study[9] Ruelle satisfied himself that paralyses may appear when the blood contains a high content of antitoxin and when the amount is actually increasing. He shows that the fixation of toxin to the nervous tissues occurs early, and that the production of antitoxin after this in no way influences the subsequent appearance or duration of paralyses. Experimental support is thus provided for the general opinion of clinicians in this country, who believe that no known therapeutic measure—physical, chemical, bacteriological, or serological—can directly influence the nervous lesions.

SPECIALIST OBSTETRIC SERVICE

INVESTIGATIONS carried out in recent years in this country by the Departmental Committee on Maternal Mortality, and in America by the New York Academy of Medicine, furnish evidence that about half the maternal deaths might be avoided if, as Dame Janet Campbell puts it in a newly published pamphlet,[10] "the necessary professional competence, the clinical facilities, the material aid, and the intelligent coöperation of the patient were available always." During the discussion on maternal mortality in the House of Commons on March 25th, Dr. O'Donovan pleaded that, before the country embarks on a widespread scheme of gynæcological clinics, the medical profession shall produce competent gynæcologists—"men with trained first-class brains"—to man them. The word clinic, he said, may cover a multitude of incompetencies, and Dame Janet follows the same line of thought when she states that a national maternity service is only likely to raise the standard of midwifery, and to reduce the toll of avoidable accidents if a selected corps of workers can be induced to participate in the scheme. While there has been steady growth both in the number of antenatal clinics throughout the country, and in the attendances made, it does not appear that there has been any appreciable effect on the maternal death-rate as a whole, though in certain selected medical and hospital practices, where the supervision is carefully organised and thoroughly carried out, excellent results have been obtained. But these practices, Dame Janet says, are exceptional, and in many places the quality of work has not kept pace with its extended scope, and a good deal of it has been "partial, insufficiently skilled or inefficient." Antenatal care has, admittedly, been less successful than its advocates hoped, and in consequence there has been a certain reaction against it; but it is not the principle which is at fault, but its application. The first great service rendered by antenatal clinics was to demonstrate the need for supervision of pregnancy alike to doctors, nurses, midwives, and the general public. They still form a valuable type of institution and one capable of expansion, but the medical officer in charge of every such clinic should be a skilled obstetrician closely in touch with practical midwifery, and some arrangement should be devised to prevent such overcrowding that a doctor is asked to deal with more patients at a session than he can attend to adequately. Dame Janet calls attention to the fact that, although all registered medical practitioners are entitled to practise in every branch of the healing art, it is generally recognised that those practising in certain special departments are expected to furnish definite criteria of skill and competence. She suggests that one of the greatest contributions which the profession could bring to the solution of the maternal mortality problem might be to insist on post-graduate training, and evidence of special study and experience on the part of doctors intending to make midwifery an integral part of their practice.

TYPHOID DUE TO SHELL-FISH

An attack on the hygienic shortcomings of the French shell-fish industry, made by an expert bacteriologist, contains information on the hygienic problems of shell-fish not to be found elsewhere. Dr. Belin's[1] interest in the subject was aroused by a tragedy in his own family following the eating of oysters. In attempting to assess the justice of the charges allowance must be made for the bitter sense of grievance, but the picture he paints carries a certain degree of conviction, enough to cause any reader who is not very courageous or very gluttonous to forswear oysters when on his next visit to France. According to Dr. Belin, no serious attempts are made in France to render safe the consumption of shell-fish. In the Mediterranean region in particular, the conditions of culture and sale are said to be unsatisfactory in the extreme. In the commune of Marseilles (654,000 inhabitants) alone, Dr. Belin estimates the number of cases of typhoid ascribed to the consumption of shell-fish is upwards of 2000 a year, and he says that the incidence falls particularly heavily upon visitors who have had no opportunity of acquiring environmental immunity. Dr. Belin's bibliography is full but by no means complete; there is no reference, for instance, to Timbrell Bulstrode's classical report of 1911 (vide THE LANCET, April 22nd, 1911, p. 1089).

It is interesting to reflect that we import a considerable number of French oysters into this country. These oysters, so far as London is concerned, are subject to the very thorough bacteriological and general control of the Fishmongers' Company, and on the whole prove a satisfactory product. It is obvious, therefore, that French cultivators catering for the English market cannot fairly be held to deserve the strictures which Dr. Belin levels against French cultivators in general. Beyond the special supervision of the London markets by the Fishmongers' Company, the regulations for the control of the sale of shell-fish are by no means comprehensive. They consist of a brief set of regulations set up by the Public Health Acts, and they make no provision for preventing the importation of contaminated shell-fish throughout the country as a whole. The vigilance of the Fishmongers' Company, combined with these regulations, however, appears to have ensured an almost complete immunity from outbreaks of enteric due to shell-fish in this country. One of the few remarks of Sam Weller which has failed to stand the test of time is his observation of the "wery remarkable circumstance that poverty and oysters always seem to go together"; this, alas, appears to be no longer true in Great Britain. It is consolation, nevertheless, to know that if we pay dearly for our oysters we can eat them in safety.

AN EIGHTEENTH CENTURY STUDY OF THE BRAIN

In 1882 a work on the brain by Emanuel Swedenborg was published, having been translated, edited, and annotated by Dr. R. L. Tafel from the original Latin MS. written between 1741 and 1744. It has now been reprinted under the auspices of the Swedenborg Society[1] and is well worth attention. The picturesque nomenclature of the eighteenth century is not the least of its attractions. The editorial annotations are of help in the interpretation of the work, and must obviously have involved a great deal of patient and learned research into the anatomical and physiological literature available at the date of publication. The peculiar genius of Swedenborg was, at the period of his life when this book was written, directed primarily into philosophical and physiological, rather than into anatomical channels. This is shown throughout the work by the constant endeavour to discover the functions of the brain and its appendages. The method used by the author was not that of original experiment, but rather of analysis of and deductions from the anatomical facts which were known in his day, combined with a study of pathological cases. He deliberately abandoned experimental research because, to use his own words: "I find when intently occupied in exploring the secrets of the human body, that as soon as I discover anything that had not been observed before I begin (probably seduced by self-love) to grow blind to the most acute researches of others, and to originate the whole series of inductive argument from my particular discovery alone"—a quotation that might not inaptly be displayed in research laboratories to-day. His method was one of induction, and shows remarkable originality of thought and outlook. Swedenborg's knowledge of contemporary anatomical knowledge was profound; but he never regarded it as an end in itself, only as a means to arrive at an explanation of the functions and mode of working of the brain. He based his physiological theories on the most minute examination of the form and relations of the parts of the brain, and some of the results he obtained are certainly striking. For example, he ascribes the motor areas of the brain to the positions now known to be the correct ones, even to the relative positions of the areas controlling the head, arms, trunk, and lower limbs. He also locates the intellectual faculties to the frontal region of the brain. In common with many philosophers of his time, he was much troubled about what part of the brain was occupied by the "soul"; he discarded entirely the theory of Descartes, largely held at that time, that the "soul" resided in the pineal body, but ascribes it rather to the cortex of the brain. From an analysis of the minute structure, as then known, of the pituitary gland, he was led to ascribe to it functions of the utmost importance in the composition of the blood, and, in fact, calls it the "arch-gland" of the body. He devotes many pages to the study of the motion of the brain, and draws the conclusion that respiratory motion is that proper to the brain itself; the pulsatile motion he regards as being primarily derived from the vessels of the dura.

INFANT MORTALITY-RATES IN VARIOUS COUNTRIES

A SOMEWHAT surprising characteristic of the decline which has been recorded in the infant mortality-rate in all European countries is an accentuation of the differences between one country and another. This feature is clearly shown in a study of infant mortality by K. Stouman, former chief statistician of the Health Section of the League of Nations Secretariat.[1] The explanation of this increased variability lies no doubt in the fact that the fall began at different periods in the various countries, and is progressing with different rapidity. Stouman sees no reason why stabilisation, when it finally approaches, should maintain the extreme national individualism now shown. At present, however, there are no signs of stabilisation, and the fall continues even in countries where the rates are lowest. Also the statistics of several countries in recent years show some improvement in the neonatal mortality, in which so far very little has been achieved. International comparisons of the neonatal mortality-rate are peculiarly difficult to make owing to the differences in definitions and registration systems. Stouman takes stillbirths and infant deaths under 1 month to represent together "birth mortality" and finds a much smaller range of variability in Europe than with the rate at 1–11 months. The former rate, he suggests, is related chiefly to vitality, the latter to surroundings, and surroundings are more subject to change than is vitality. One effect of the greater decline in the rate in the second six months of life is an increase in the excess of the male over the female mortality-rate—for the male excess is greater in the first six months of life and must grow larger as the proportion of early deaths increases. Thus a rise in the male excess may be taken, Stouman suggests, as a sign that the "selective" forces in a country (those determining mortality in the first month) are gaining on the "destructive" forces (those determining mortality at 1–11 months). In England and Wales the infant mortality-rate is appreciably higher in the towns than in the rural areas. This is not, however, a general feature of infant mortality. The rate is now lower in towns in most of Central Europe—in the Netherlands, Belgium, Bavaria, and Switzerland particularly. Statistics from Holland, Denmark, and the United States show that the rural excess is at its maximum in the second and third months of life. It seems to be at this point of infant life, Stouman remarks, that the greatest achievements have been realised by the more active health services of the large towns. It follows that the health services of rural districts, as well as of large towns which are still somewhat behind in this respect, would do well in directing their attention toward the problems connected with infant life during these critical months.

NITROGEN RETENTION AT THE ONSET OF SCARLET FEVER

THE renal complications of scarlatina fall into several categories. At the height of the fever albuminuria is encountered in a considerable proportion of patients, it is usually benign, and it is even doubtful whether it can properly be considered an index of true involvement of the kidney. Focal nephritis, characterised by intense hæmaturia and a benign course, occurs rarely, also during the period of fever. The classical acute nephritis of scarlatinal origin is usually encountered towards the beginning of the third week of the disease; Barasch in an analysis of 121 examples, showed that 90 of them had their onset in the third or fourth week of the disease. Suppression of urine sometimes occurs at the very outset of scarlet fever, especially in the more malignant types of the disease; usually fatal in the severer cases, it may subside completely after a few days, it is doubtful whether this complication is a true nephritis or whether it represents an arrest of the renal circulation from purely nervous causes.

Recent work suggests that nitrogen retention, without gross alteration of the volume of urine secreted, and often without albumin in the urine, occurs in a proportion of all cases of scarlet fever. This interesting fact has been closely studied by A. Lemierre.[1] At the Hôpital Claude-Bernard in Paris they have observed in 49 cases of scarlet fever of varying degrees of severity a normal blood nitrogen or a mild degree of elevation of the blood nitrogen falling to normal after several days. In 8 cases the blood-urea was raised to about 60 mg. per 100 c.cm. at the onset of the disease and fell below 50 in from two to four days, but in 4 other cases the blood-urea was found considerably elevated, in the region of 100 mg. at the outset, and rose in several of them to a figure of nearly 300, falling slowly from this figure to return to normal after some weeks. During the period of observation these cases were passing an approximately normal amount of urine from which albumin was completely absent or demonstrable merely as an occasional minimal trace; the blood pressure was not raised and the only other outstanding facts were dryness of the tongue, a tendency to vomiting and diarrhœa, and a condition of prostration with occasional mental excitement out of proportion to the general condition of the patient. All these cases cleared up spontaneously, although recovery was delayed in two of them, and careful tests of renal function during convalescence showed that the kidney emerged without permanent impairment. On the question whether these cases should be considered as examples of nephritis or whether they merely represent some form of extrarenal nitrogen retention Prof. Lemierre is very guarded. He recalls that oliguria is almost universal at the onset of scarlatina, and that this by itself may be an index of renal insufficiency; the virus of scarlatina, like other toxins, provokes to some extent a breakdown of the proteins of the body tissues, and this circumstance will also tend to increase the blood nitrogen. There are therefore several factors tending to produce the phenomenon he has studied. But even though it is very possible that this nitrogen retention is evidence of a purely functional disturbance it remains a strong indication for a low protein diet at the onset of the disease, combined with an abundance of water. Prof. Lemierre holds also that the salt-intake should be strictly regulated, since his observations indicate that the elimination of sodium chloride by the kidney is definitely interfered with during the febrile period.

ROYAL MEDICAL BENEVOLENT FUND

THE annual general meeting of the Royal Medical Benevolent Fund was held on Wednesday, March 27th, at the rooms of the Medical Society of London, Sir Thomas Barlow presiding. The report for the year ending Dec. 31st, 1934, was read and adopted, and its contents showed real progress. There was during 1934 an increase of income of £1676, while 869 new subscribers were enrolled—both figures constitute a record. The number of persons directly connected with the medical profession who were individually helped during the year was 670, and there was paid out by the Fund in quarterly, monthly, or single payments during the period £18,415. The particulars concerning many of the beneficiaries are stated from time to time in our columns, proving the existence of the Fund to be vital. "At present," says the report, "their needs can be met only by an annual grant of £40 to a medical practitioner and £26 to a dependent. Not until the Fund has the full support and sympathy of every member can the profession feel confident that misfortune in its own ranks can be adequately dealt with by this medical charity." All who read the details of individual cases helped, as they are recorded in our columns, will see how often the help granted is insufficient to the needs. So we would endorse with emphasis the words quoted from the report. The Fund does admirable work directly, and by means of its Ladies' Guild, through which organisation personal service is given in the shape of the allocation of medical comforts, gifts of clothing and coal, pecuniary grants and arrangements for holidays; the Guild indeed brings to the beneficiaries of the Fund most valuable succour.

The centenary of the Fund will occur in 1936, and we learn from the report that careful consideration is being given by the committee of the Fund as to the manner in which the occasion should be celebrated. The committee believe that it would be the unanimous wish of the profession that no application should be made in any form to the public for assistance but that, as in the case of the benevolent funds of other professions, the appeal should be made only to members of the profession. This is an attitude which should commend itself to all of us, and affords a most forcible argument for further subscriptions to the charity, for until the Fund has a full backing by the medical profession recourse to public benevolence can with difficulty be justified. We therefore bring to the notice of our readers the following facts: the Royal Medical Benevolent Fund meets urgent needs; its money is distributed upon careful scrutiny and with every practical expression of sympathy; it is not duly supported; records exist only to be broken; the secretary of the Fund, Mr. E. C. Pennefather, M.B.E., can be addressed at the office of the Fund, 11, Chandos-street, London, W.1, and his acknowledgments are made by return of post. If this were being written in America it might well end "Attaboy"; one may translate the picturesque expression into the phrase, "Please subscribe and subscribe quickly."

HYDATIDIFORM MOLE

A FORTNIGHT ago we reported a meeting of the obstetric section of the Royal Society of Medicine at which Mr. Alan Brews described a study of 72 cases of hydatidiform mole admitted to the London Hospital since 1912. Almost coincidently comes a study of 78 cases by J. T. Sherman,[1] and the two series may profitably be compared. The writers agree that the cause lies in the ovum rather than its environment; and Brews describes a twin pregnancy consisting of a normal placenta and fœtus and also a hydatidiform mole. In some respects, however, there is a profound difference in the findings. Thus Brews notes that 37 per cent. of his cases were in women over forty, whereas of Sherman's series only 10 per cent. were above that age. Again, Sherman states that chorion-carcinoma very rarely follows hydatidiform mole, but as only 12 of his patients were followed up and one of these developed it, his evidence cannot be held adequate. Brews, who was able to trace all but 17 of his series, found that no less than 6 cases, or 8 per cent., developed chorion-carcinoma. The mortality was low, about 2 per cent., in both series, and treatment was uniformly conservative in that whenever possible the uterus was allowed to empty itself. In a substantial proportion of cases (Sherman 7 per cent. and Brews 20 per cent.) the uterus was observed to be smaller than would have been expected from the probable duration of the pregnancy—a finding contrary to the usual text-book description. Both investigators report a high incidence of toxæmia (about 1 in 3) and both emphasise the value of the Aschheim-Zondek test as an aid to diagnosing the condition itself and as a means of excluding the subsequent growth of a chorion-carcinoma. Other observers (see p. 812) have found the test capricious.

On Wednesday afternoons, from April 24th to June 26th, at the Institute of Medical Psychology, Dr. H. Crichton-Miller and Dr. Cedric Shaw are lecturing on problems relating to psycho-physical adaptation. The address of the institute is Malet-place, London, W.C., and further information may be had from the secretary. These lectures constitute an introductory course for practitioners.

THE firm of Hodder and Stoughton, the proprietors of THE LANCET, has never taken in a new partner or a new director other than direct descendants of the founders of the firm, Matthew Henry Hodder and Thomas Wilberforce Stoughton. Mr. R. Percy Hodder-Williams (the present chairman of the firm) and his brother, Mr. Ralph Hodder-Williams, announce that they are now appointing to the directorate two of their nephews, Paul Hodder-Williams and John Attenborough, great-grandsons of M. H. Hodder, the original senior partner of sixty-seven years ago.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL.—Owing to the demand on the accommodation of this hospital in its present building in Marylebone-road, it has been decided to press on with the work of building the first wing of the new hospital at Ravenscourt-park. The cost of the first stage will be £60,000.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XLVI.—PROGNOSIS IN GENERAL BIRTH INJURIES

In the course of parturition some trauma to the female birth passages is almost unavoidable; usually this is slight and little or no appreciable discomfort follows, but in some cases the injury is grave and may produce varying degrees of disablement or even death.

The prognosis as regards the future health and fitness of the mother in such cases is influenced by many factors, of which the type of treatment adopted is of the first importance. It is this aspect of the matter that will be considered here.

DAMAGE TO PELVIC FLOOR

Damage to the pelvic floor is one of the most common of these lesions and the most usual variety is laceration of the perineum. The prognosis depends mainly on whether the perineal body and the levator muscle are injured and whether the laceration is promptly and properly sutured. It is not possible to perform a proper repair unless a good light is available and unless the limits of the laceration are clearly demarcated. If the laceration has involved the deep structures, a layer of deep interrupted sutures should be inserted in the first place. Merely to suture skin and mucosa will give no support however neat the wound may look. If this be done, even if some breaking down should subsequently occur, a strong perineal body will eventually result, as the perineal tissues have the faculty of progressive healing for several weeks. Immediate suture is especially necessary if the laceration has extended into the anal canal, otherwise rectal incontinence may ensue. In some apparently complete repairs everything may heal except a small fistulous communication a little way up the posterior vaginal wall, which may cause only an occasional leak of flatus or liquid fæces with corresponding social inconvenience. In this case a subsequent plastic repair is necessary, and in experienced hands nearly always gives satisfactory functional results.

REMOTE EFFECTS

The results of perineal damage may manifest themselves only in later years, at and after the menopause, by the occurrence of various degrees of pelvic floor weakness and prolapse. While the degree of probability of the occurrence of prolapse long after parturition cannot be foretold in any individual case, it is certain that the main predisposing factor to such an event is failure to effect repair of such tissues of the pelvic floor as may be damaged at that time.

The question arises whether a repaired perineum is likely to break down at future labours. The answer is that if the conduct of such labours is unhurried, in over half the cases no further laceration need be anticipated. Should it occur it can be resutured, but admittedly if this has to be done on several occasions the perineal tissues tend to become progressively weakened, with the corresponding probability of subsequent prolapse. In this connexion it has to be remembered that the perineal tissues may be stretched and weakened even in normal labour, without any surface laceration. In such cases the probability of prolapse later is considerable and nothing can be done to prevent it. In cases seen in later years when the various varieties of pelvic floor weakness—cystocele, rectocele, or prolapse—have developed the best prognosis lies in a properly planned repair operation. Only when consent is withheld or some contra-indication to operation is present should pessary treatment be advised. Pessaries cannot effect a cure of prolapse; they are mere vaginal mechanical supports which cause irritation and discharge and call for douching and periodical changing while they are often ineffective.

The type of operation required naturally varies according to the local condition, but in a complete prolapse treated by the Fothergill-Donald operation failure should occur in not more than 2 per cent. of cases (Fletcher Shaw), so that the prognosis as regards increased future comfort and efficiency is excellent.

RUPTURE OF VAGINA

Rupture of the vagina apart from perineal laceration usually occurs in the upper part of the postero-lateral wall. It is almost always due to undue force on the part of the attendant and may be associated with laceration of the cervix. The prognosis is grave on account of the peritoneum being opened, with prolapse of loops of bowel into the vagina. In half the cases the patient is too shocked to allow proper suturing and the best that can be done is to cleanse the vagina and the prolapsed bowel and to pack firmly. Seventy-five to eighty per cent. of these cases die of peritonitis within three days from the effects of trauma and associated sepsis.

LACERATION OF THE CERVIX

Some laceration of the cervix occurs in practically every full term labour and the late results of this lesion constitute about 70 per cent. of all cases seen in gynæcological clinics. Such laceration is usually slight in normal labour, but as the result of manipulations, especially with an imperfectly dilated cervix, deep lacerations may be produced extending up to the vaginal fornices and possibly involving the base of the broad ligaments. It is often said that the slighter degrees of cervical laceration heal spontaneously and are of no account (Whitridge Williams); but modern obstetric opinion does not favour this view. On account of trauma, muscular separation of the lips of the laceration, and superadded infection the lesion, however small, hardly ever heals but produces the common condition of chronic cervicitis with its numerous extensions and symptoms.

In all cases, then, of even slight laceration the prognosis as regards future symptoms and possible disablement owing to parametritis, metritis, or salpingo-oöphoritis may be serious, and when it is remembered that it is on the traumatised cervix that carcinoma is engrafted in later life, it is evident that in a certain small proportion of cases the prognosis is very grave. It is, however, impossible to prophesy which individual will do badly. Adequate prophylactic treatment is made difficult by the impossibility of suturing every small surface laceration after labour; a deep laceration can and should be sutured either then or some ten days later, but extensive lacerations are not common and are no more likely to be followed by chronic infective symptoms or by carcinoma than is a small and apparently unimportant tear. It cannot be over-emphasised that the prognosis in these cases depends not at all on the extent of the original laceration; the degree of trauma and subsequent infection are the important factors and can seldom be estimated at the time of labour.

INVERSION OF THE UTERUS

Inversion of the uterus is only rarely encountered even in hospital practice. In the last ten years I have seen only six cases. It may occur spontaneously but more often there has been excessive kneading of a slack uterus with a patulous cervix; traction on the cord is often quoted as a cause but it does not appear to have been associated with most of the recorded cases.

Prognosis is influenced by several factors :—

(1) The *acuteness of the condition.*—Should inversion occur before or immediately after the expulsion of the placenta shock is marked. Hæmorrhage may also be severe but the degree of shock has no relation to the amount of bleeding. Should the inversion not appear for several days the element of shock may be slight or absent with a correspondingly improved prognosis.

(2) The *supervention of sepsis.*—Should sepsis occur the outlook is usually bad, and as one of the main causes of this condition is strangulation of the inverted fundus by cervical constriction it is certainly to be feared.

(3) The *method of treatment.*—In general the uterus should be replaced in position under anæsthesia as soon as possible, but in extremely shocked patients such manipulation may only increase the shock already present and may be fatal. Nice judgment is required in determining the proper course of action, and the prognosis is greatly influenced by the wisdom of the obstetrician in charge of the case.

In general, the prognosis has been improved in recent years by better obstetrics; thus J. G. Crosse in 1843 reported 109 cases with 80 deaths, while the present mortality can be reckoned at 14 to 20 per cent. (R. D. Maxwell, P. Findlay, L. Beckmann). W. Zangemeister found that reposition within 1 to 24 hours after the inversion yielded the best results. Of our six cases in Cardiff all were replaced without difficulty, but two died, one of shock and one of sepsis.

RUPTURE OF THE UTERUS

Rupture of the uterus may occur in late pregnancy either spontaneously or through the scar of a previous Cæsarean section; it is then usually in the upper uterine segment. More often it occurs in prolonged and obstructed labour due to thinning of the lower uterine segment, and then the rupture is in the lower part of the organ. The prognosis for the mother is always grave and is influenced by the liability to shock, hæmorrhage, and peritonitis. The sooner laparotomy is performed, the fœtus and placenta removed, and hysterectomy performed, the better the outlook. If operation is undertaken within two hours of the rupture a case-mortality rate of under 40 per cent. may be anticipated, while after that interval the rate is fully 75 per cent. The nature of the rupture also influences the prognosis. In the complete variety into the peritoneal cavity a death-rate of 70 per cent. is to be expected, while in the incomplete variety, in which the rupture may not be through the peritoneum or may be into the base of the broad ligament, hæmorrhage is not so free and the mortality ranges from 15 to 20 per cent. Unsuccessful and traumatic attempts at delivery in obstructed cases influence the prognosis adversely by the production of bruising and laceration, with corresponding predisposition to subsequent sepsis. According to J. B. de Lee the prognosis in these cases depends on so many conditions that figures are practically valueless; in his series of 18 cases of complete rupture 11 died, while in 19 cases of incomplete rupture only 3 died. These and similar figures quoted by others are in general agreement with the prospects stated above. The fœtus is practically always dead, only three live cases having been reported.

FISTULÆ

That fistulæ are not common nowadays demonstrates, in spite of all that may be said to the contrary, improvement in present-day obstetrical practice. They usually occur after prolonged labour, and are produced by too prolonged pressure of the presenting part on a localised area of vaginal mucosa with subsequent sloughing; less commonly they are produced directly by instrumental perforation.

Rectovaginal fistulæ usually occur in the lower part of the vagina and represent an unhealed area in the upper part of a previous complete perineal tear; much more rarely they occur in the upper vaginal mucosa. The tendency in a rectovaginal fistula is always in the direction of healing, so that fully 30 per cent. will close spontaneously if given time. Operation therefore is not advisable within three months from parturition. When it is required, it usually takes the form of a complete perineal repair including the fistula and, with proper technique, fully 80 per cent. of such cases heal at once; in the upper vaginal fistulæ a plastic operation usually suffices, and only rarely is separation and suture from above by laparotomy required. It has to be remembered that even should the fistula break down after operation, the tendency to healing will remain so that in a few weeks over 50 per cent. of the cases will heal by granulation.

In *vesicovaginal fistulæ*, on the other hand, the conditions are reversed. The fistula is continually bathed in urine which may be infected, and the lips tend to become epithelialised so that spontaneous healing is not to be expected, and indeed occurs very rarely. A plastic repair operation is practically always necessary, and the likelihood of a breakdown with recurrence of the fistula is so great that cure cannot be promised. A number of operations may be necessary before the fistula is closed. Operation should be deferred until the edges of the wound are clean; the presence of bruising, of infected urine, or of phosphatic deposits on the fistula inevitably presage operative failure. The prognosis is influenced by the number of previous operative failures; thus A. Apajalahi found healing in 60 per cent. of cases after the first operation, in 30 per cent. after the second operation, in 24 per cent. after the third, and in 10 per cent. after the fourth operation, while no cases healed after the fifth operation. A review of statistics collected by Simon, Frank, Bey, Saenger, and others shows between 70 and 80 per cent. of operative cures in these fistulæ, but in the hands of those who are not specialists in this work not more than 50 per cent. of cures is to be expected.

CONCLUSION

It will be seen from what has been said how diverse may be the results and effects of genital birth injuries, and how multiple are the factors which influence us in arriving at a prognosis; also that the choice of appropriate treatment has an important influence on prognosis. The advantages of prevention over even the most satisfactory cure of any such injuries is obvious.

MEDICINE AND THE LAW

Damages for Negligence against Osteopath

THE award of £1500 damages against an osteopath last week (in Smith *v.* Lowry) shows once more the danger of ignoring the resources of X ray photography. The allegation of negligence against Captain Lowry, the defendant, was that in manipulating the left leg of the child Sheila Smith, he fractured the neck of the femur and caused a permanent restriction of the left hip. There was evidence that the child suffered previously from displacement of the left hip which an X ray photograph would have revealed, and that manipulation which would cause no injury to a normal child might fracture the thigh of a child suffering from displacement. Thus, as the judge observed to the jury, the taking of the photograph would have warned an operator that the patient needed to be handled carefully.

Captain Lowry lost his sight at Neuve Chapelle in 1914. He was the first blind man to qualify as a masseur from St. Dunstan's, and he has practised as an osteopath since 1925. He claims with justification to have developed a remarkable sense of touch. It was not suggested that his disability of sight caused the injury to the plaintiff. There was considerable conflict of testimony on matters of fact, but there was indisputable evidence in the form of radiograms. For seven weeks in July and August, 1930, Sheila Smith was under treatment at the Royal Free Hospital; a radiogram taken at this period showed a displacement of the right hip bone. Captain Lowry operated upon Sheila in August, 1931; a radiogram taken next day showed a fracture of the neck of the left thigh bone. There was no explanation of the fracture except that it occurred during Captain Lowry's manipulation. There was medical evidence that the girl is now crippled for life from the combined effect of the fracture and the earlier displacement.

The story of the mother was that Sheila had some form of rheumatism and had put on weight. Having read that Captain Lowry had cured a girl of over-weight, the mother took Sheila to see him. She said—though this he strongly denied—that he ridiculed the doctors' diagnosis of rheumatism, that he spoke of mistakes made by clever surgeons in London, and that he declared there were no signs of rheumatism but merely a slight dislocation of the left hip and a twisted intestine; this he said he could put right by a very slight operation. There was great conflict about the child's ability to walk. Seven witnesses said she could walk perfectly well; the girl herself said she went for a walk before the operation and climbed unaided on to the operating table. On the other hand, Dr. H. Chodak Gregory of the Royal Free Hospital was clear that Sheila had a noticeably "waddling" gait in 1930, and Captain Lowry's secretary noted on Sheila's case-card that the child was carried into his house for the operation in 1931 with great pain in her left leg. On August 25th the operation proceeded under an anæsthetic. The mother said she was present and heard a cracking sound, after which Captain Lowry remarked "that was a funny noise"; Captain Lowry denied this and said the mother was not present. There was apparently no dispute that the child was taken home in great pain, that the mother twice telephoned anxiously to Captain Lowry next day, and that he sent a radiographer to the Smiths' house and later sent a surgeon (Mr. Noel St. J. D. Buxton of King's College Hospital and the Royal Waterloo Hospital), whose subsequent treatment of the patient involved placing her in a plaster-of-Paris splint for three months and an operation in the following February to correct the position of the neck of the right hip bone. Captain Lowry also sent his wife to see Mrs. Smith soon after the radiographer's results had disclosed the fracture. The plaintiff apparently relied on some of these incidents as indicating that the defendant was conscious of unsuccessful treatment; they were equally explicable as manifestations of ordinary sympathy. Captain Lowry's version differed from Mrs. Smith's. He said that nothing untoward occurred while he was manipulating the patient's limb; that he used no violence but was merely making an examination; that he required an anæsthetic for the examination because the child was nervous; that he broke off his examination and told the anæsthetist that it was a case for a surgeon; that he was not at all perturbed about Sheila afterwards, and that he sent a surgeon to examine her out of kindness of heart, offering to waive his own fees and to pay the surgeon's fee, which Mrs. Smith could repay him later. In summing up to the jury, Mr. Justice Talbot observed that, if Captain Lowry's evidence was correct, certain passages in the evidence for the plaintiff must have been fabricated. The verdict of the jury indicates the belief that Captain Lowry caused the fracture and that he was at fault in doing so.

SIDELIGHTS ON THE CASE

Among other features of the case, not perhaps of special relevance to the jury's task, it may be noted that Captain Lowry, an unqualified practitioner, employs a duly qualified anæsthetist. As a general rule, he stated in his evidence, it was unnecessary to use anæsthetics in osteopathy. He was asked in cross-examination if it was within his knowledge that the British Osteopathic Association had constantly complained of his use of anæsthetics. He replied that it was untrue. In opening his defence his counsel stated that Captain Lowry was not going to expose his anæsthetist to disciplinary proceedings by calling him as a witness. Captain Lowry would sooner lose the case than let down the medical practitioner who has trusted him. Captain Lowry would not even disclose the doctor's name unless compelled by the court; he had the name in a sealed envelope and would hand it to the judge if so compelled. This was perhaps a forensic flourish of no great importance. Captain Lowry had doubtless given personal undertakings against disclosure to any registered practitioner who, with his eyes fully open to the risk, assisted an unqualified man. The court was not likely to compel the defendant in a civil action to call any witnesses whom the defendant for whatever reason decided not to call.

Captain Lowry's own status and qualifications were explained by him in the witness-box. He had attended lectures on anatomy at Middlesex Hospital and St. Thomas's Hospital while studying massage. He had not attended any lectures on surgery. He had formerly been a member of the British Osteopathic Association, but had retired after being summoned before that body to explain the appearance of his name in a newspaper. He had, it seemed, differed from the Association as to his right to advertise a book which he had written entitled, "From Mons to 1933." He was a member of the Incorporated Society of British Osteopaths. He denied that he had recently claimed, in lectures in America, the development of a sixth sense which enabled him to diagnose cases which medical men failed to diagnose. Mr. Justice Talbot, in summing up to the jury, said that Captain Lowry had evidently held himself out as having considerable skill; along with such claims went the duty to use care. The judge did not fail to express the admiration which all will share for the courage and success with which Captain Lowry, after losing his sight in his country's service, has addressed himself to a fresh career.

The case will no doubt be studied in relation to the legislative proposals for the recognition of osteopathy now under examination by a committee of the House of Lords, and reported in our Parliamentary columns.

Dangers of the Calender

That the possession of a calender machine may be a serious liability to a mental hospital was disclosed in an action tried by Mr. Justice Horridge on March 20th. A former employee in the laundry of the Goodmayes Mental Hospital, administered by the West Ham Borough Council, was awarded £695 damages and costs for injuries due to insufficient fencing, contrary to the provisions of the Factories and Workshops Acts, of the calender on which she was working. A calender is a wringing machine with hot rollers, which irons clothes as it dries them. Hitherto, in designing safety-gear, the makers and users seem to have assumed that the danger-point is the rollers. To prevent an employee's hand from being caught in these, the calender is fitted with a kind of shutter a few inches high, which extends across its whole width, and guards the approach to the rollers. The employee places the folded wet clothes on an arrangement of moving tapes which carries them beneath this guard to the jaws of the rollers; an incautious hand travelling with the clothes must press the guard back, and a movement of about an inch operates a trip mechanism which stops the machine. The story of how, in spite of this device, the laundry-maid sustained a broken little finger and extremely bad burns, necessitating the amputation of the little finger with its metacarpal bone, makes solemn reading for mental hospital governors. The employee saw a nightdress going in with one of the sleeves inside-out; she put her hand in to straighten the sleeve, but by this time the lower part of the sleeve had passed under the guard and was in the rollers; the sleeve tightened round her hand and she could not withdraw it. The guard of this machine, instead of being perpendicular, curved inwards towards the rollers about two inches. It operated the trip mechanism after her hand had moved it about an inch but, owing to the ordinary lag in the brake of the machine, the rollers moved onwards a little over an inch more after the power was shut off, and the gap left by the guard was sufficient to allow her hand to be pulled in until the little finger went either into or very near the nipping point of the rollers. That it was broken suggests that it was actually caught. Leading to the rollers there is a narrow hot plate at about the same temperature—well over boiling point; her hand was held tightly down on to this plate by the sleeve in which it was entangled, and she suffered ten minutes of what must have been excruciating pain before she was released. The hot plate rather than the rollers, as the judge remarked, was in this case the dangerous part of the machine which was insecurely fenced, and he suggested that such accidents could be avoided if the guard were placed so far from the plate that no hand could possibly reach it before the machine was stopped. Queerly enough, the calender is one of the few exceptions to the general rule that machinery is delivered to the user unfenced; in this case—perhaps in recognition of the inherent danger of the machine—the fencing is done by the makers themselves. This does not seem to be an isolated case; accidents with those machines are no rarity. The present decision is subject to appeal, but the possibility of having to pay heavy damages for the shortcomings of the safety-gear should induce mental hospitals and other institutions to take serious thought for its efficacy in the future.

Bequest to Non-existent Hospital

It is a pity that charitably minded persons sometimes omit to identify the institutions they desire to benefit. Last week Mr. Justice Farwell was asked to decide what should be done with a substantial legacy bequeathed to "the King Edward the Seventh Royal Hospital, London," there being no hospital of that name in London. The testator, Mr. William Hurst, of Little Hulton, in Lancashire, was a retired publican who had prospered in business, and whose bequest amounted to £42,440. So far as was known, he had never visited or subscribed to any hospital in London. He had frequently expressed his admiration for the personality of King Edward VII. and, as Mr. Justice Farwell observed, he must have supposed that there was some hospital in London named after him. Four institutions filed affidavits in support of their claims for consideration; in each case the judge found some ground for rejection. The King Edward's Hospital Fund was excluded because it was not a hospital. The King Edward VII. Hospital at Windsor was ruled out because it was not in London. The same objection was fatal to the King Edward Memorial Hospital at Ealing. The King Edward the Seventh's Hospital for Officers (founded by Sister Agnes) was a London hospital, but not a general hospital. Having thus disposed of the various claimants, the judge withdrew from the court to enable the parties to reach a settlement. Besides the four institutions already named, the next of kin was represented by counsel and, since he is officially interested on behalf of the public, the Attorney-General also appeared. On the judge's return to court it was stated that, subject to the deduction of a certain sum and the estate duty thereon which it had been agreed should be paid to the next of kin, his lordship would be asked to direct a scheme in Chambers for the administration of the fund. Mr. William Hurst, we must suppose, made his own will. It would have been the duty of his legal advisor, had he employed one, to see that the objects of his charitable intention were specified with certainty.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

EDINBURGH UNIVERSITY

AT a meeting of the university court of the University of Edinburgh, the court and senatus resolved to present an address to the King on the occasion of the celebration of the Silver Jubilee. The court also agreed to grant permission to the Corporation to make arrangements for the flood-lighting of the dome of the Old College on the occasion of the celebrations. The principal, Lord Blanesburgh and Sir Norman Walker were reappointed as the university representatives on the curators of patronage for the period to Nov. 30th, 1937.

The court approved the regulations for the award of the Shaw Macfie Lang fellowship in 1935. The fellowship, of the annual value of £215 and tenable for two years, will be open for competition in [illegible], 1936, to graduates who have taken the degrees of M.B., Ch.B., with honours, in any of the four Scottish universities at a date not more than five years previous to July, 1936. The successful candidate will be required to undertake research work approved by the faculty of medicine. The court also approved of the establishment of a Sharpey Schafer lectureship in physiology, a fund for the endowment of this lectureship having been contributed by pupils and friends of the late Sir Edward Sharpey-Schafer. The first of the lectures, which will be given biennially, will be delivered in the summer term of 1935.

AN INSTITUTION FOR MENTAL DEFECTIVES

Dr. R. D. Clarkson's devoted work as medical superintendent of the Royal Scottish National Institution for Mental Defectives at Larbert is much appreciated in Scotland. Dr. Clarkson has for many years emphasised the need for a colony for *adult* defectives, and it is gratifying to know that such a colony has now been established under his supervision. At the annual meeting held recently he said that the report submitted was one of the most satisfactory in the 75 years of the institution's existence. The new adult colony will meet what has always been one of the great needs of the mental defective, for there are many, who after being trained to a certain extent, cannot be suitably provided for in their own homes and yet cannot be allowed to go out into the community. For these people the work on the farm and in the workshops of the colony affords an opportunity of feeling that they are doing some work that is worth doing, and it gives them a sense of satisfaction they cannot get in any other environment.

Dr. Clarkson does not think there is any adequate evidence that mental deficiency is increasing; he does not think there are any more mentally defective persons to-day than there were when he began his work forty years ago. He considers it cruel and inaccurate to maintain that mental deficiency is hereditary. Very few of the parents of the patients in the Larbert Institution are certified defectives. John Thomson, Leonard Findlay, and Charles M'Neil have all, he holds, proved that heredity plays only a small part in the ætiology of mental deficiency, and Dr. Clarkson is quite certain that a very large proportion of the cases are caused by injury to the brain at birth.

INFLUENZA IN 1934

A report published by the Department of Health for Scotland on incapacitating sickness in the insured population for the year ending June, 1934, analyses information extracted from medical certificates received by all approved societies operating in Scotland. Incapacities attributed to influenza numbered only 35,652, whereas the figure for the twelve months ending June, 1933, was 109,462. There was also a decrease in the incidence of bronchitis and pneumonia, but a definite increase in the amount of incapacity attributed to tonsillitis, scarlet fever, erysipelas, diphtheria, acute and subacute rheumatism, and superficial septic and inflammatory conditions. A striking feature of the statistics is the reduction of incapacitating illness among married women. In the past three years there has been an annual average decline of some 2000 cases of incapacitating diseases and this reduction does not apply to single women and men.

THE NATIONAL HEALTH

The report of the Department of Health for 1934, which has just appeared, shows a death-rate lower than any on record—namely, 12·9 per 1000. The principal causes of death were heart disease (11,427), cancer (7558), cerebral hæmorrhage (6618), pneumonia (4533), and tuberculosis (3704). The infant mortality-rate was 78 per 1000 registered births and is the lowest recorded. The birth- and marriage-rates showed a slight increase on those for the previous year, but the birth-rate is about half what it was sixty years ago. The maternal death-rate was 6·2 per 1000 live births, and is slightly higher than during the previous year.

More houses were contracted for and put in hand than in any year since State-aided housing began in 1919, and the output of completed houses in 1935 should be exceptionally high. An investigation was conducted by the Department to ascertain the views of tenants of local authority houses in the suburbs of large towns on the relative advantages of life in suburban and central areas. The views of 500 families were taken, and 429 families declared in favour of suburban as against city life. Consideration for the children was the outstanding reason for this preference for the suburbs, and a number of wives spoke of improvement in their husband's habits and sense of domestic responsibility. The most frequently expressed objection to living in the suburbs was that of travelling expenses, particularly where young boys or girls have to pay a large proportion of their small wages in fares.

The Department have watched for any evidence of the effects of unemployment on health. They could find no marked manifestation of ill-health or actual physical disease attributable to unemployment, but an abnormal prevalence of nervous conditions among unemployed men is reported. These nervous conditions tend to subside after long periods of unemployment.

EDINBURGH MATERNITY HOSPITAL

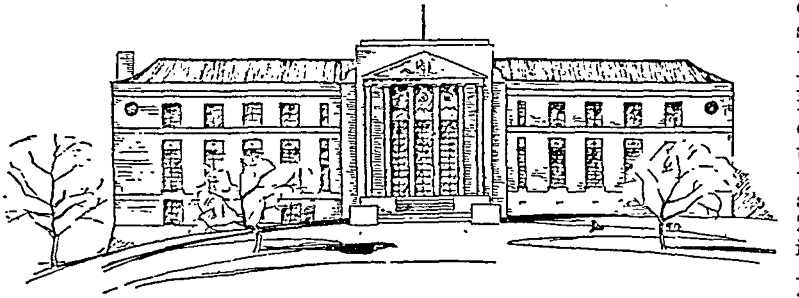
The Edinburgh Royal Maternity and Simpson Memorial Hospital held its 90th annual meeting last week. During 1934 the number of cases, intern and extern, treated by the hospital totalled 3500, and the visits to the antenatal and other clinics numbered 17,210. Of all the births in Greater Edinburgh during the year, 43·7 per cent. were dealt with in connexion with the hospital. As in previous years, the expenditure was greatly above the income, and the reserve fund had to be drawn upon to the extent of £3143.

WARRINGTON INFIRMARY AND DISPENSARY.—The finances of this institution have improved during the past year and the waiting-list of patients has been reduced from 330 to 180. Over 200 patients have passed through the nursing-home, which provides accommodation for 25 patients, private and semi-private, at fees ranging from three and a half guineas to five guineas. The cost per occupied bed in the infirmary was £143 2*s.* 8*d.* in 1934 as against £141 10*s.* 7*d.* in 1933.

ROYAL WATERLOO HOSPITAL.—The 110th court of governors of this hospital was held at the Mansion House on March 18th. Sir Stephen Killik, Lord Mayor of London, who presided, said that till the London County Council decided on its programme of development in the area to the south of Waterloo Bridge nothing could be done in the matter of the hospital's new out-patient department. During the past year 15,490 new out-patients who had been treated registered 80,747 attendances. The hon. treasurer said that the accumulated deficit of the hospital had increased to £4845 during the year. Dr. Gerald Slot spoke of pioneer work lately done at the hospital on the gold treatment of rheumatism.

ROYAL AUSTRALASIAN COLLEGE OF SURGEONS

ON the afternoon of March 4th the door of the College's new building at Melbourne was opened by Sir Holburt Waring, P.R.C.S. Eng., with a golden key given to him by Mr. L. F. Irwin, the architect. Sir Henry Newland, president of the college, took the chair at the meeting which followed, when Sir Holburt read messages of congratulation from the King and from the Royal College of Surgeons of England. Sir Henry Newland expressed thanks to Sir Stanley Argyle, the premier of Victoria, and to Mr. Hogan, a former premier, for granting the College the lease of the site at an annual rental of £1. In reply, Sir Stanley announced that the surrounding gardens were to be maintained by the city council and that he had been asked to name them College Gardens. An address entitled How Surgery came to Australasia was then given by Sir D'Arcy Power, another of the visitors from England.



In the evening Sir William Irvine, lieutenant-governor of the State of Victoria, opened the eighth annual meeting, and reminded his listeners that on the last occasion when he had done so, in 1932, Mr. C. H. Fagge had presented the silver mace which he had brought from the Royal College of Surgeons of England as a gift from brothers to brothers. Sir Henry Newland proceeded to confer the honorary fellowship of the College on Sir Holburt Waring and Sir D'Arcy Power (representatives of the Royal College of Surgeons of England), Mr. Henry Wade and Prof. J. Fraser (of the Royal College of Surgeons of Edinburgh), Dr. D. C. Balfour (president-elect of the American College of Surgeons), Dr. Dean Lewis (professor of surgery at the Johns Hopkins Medical School, Baltimore), Mr. C. F. M. Saint, F.R.C.S. (professor of surgery in the University of Cape Town), and Mr. F. Wood Jones, F.R.C.S., F.R.S. (professor of anatomy in the University of Melbourne). Sir Holburt afterwards presented the Jacksonian prize of the Royal College of Surgeons of England for 1933 to Dr. E. S. J. King, of Melbourne.

Prof. Wood Jones, delivering the third George Adlington Syme oration, spoke on the Great Master Surgeon, a type which, he said, specialisation and improved technique had, since about 1850, made less easy to recognise. He believed that though anæsthesia and asepsis had now made surgery comparatively easy and safe for all competent operators, the inspired master did exist to-day though he might be hidden among the many.

From March 5th to 8th scientific meetings, discussions, and demonstrations were held, including lectures by Dr. Balfour (the surgical treatment of duodenal ulcer), Prof. Edward Archibald (the operative treatment of pulmonary tuberculosis), Mr. Henry Wade (renal tumours), Mr. S. Harry Harris (posterior segmental block-excision of the bladder-neck with primary closure), Dr. Dean Lewis (ovarian hormones and their relation to breast tumours), Sir Louis Barnett (deaths from hydatid disease), Prof. John Fraser (lipoid disease of bone). A discussion on post-graduate education in surgery was opened by Sir Holburt Waring, Prof. Saint, and Mr. Alan Newton, and a report on the results of the treatment of carcinoma of the breast was presented by fellows of the College.

HISTORY OF THE COLLEGE

The formation of an Australasian College of Surgeons was suggested by Sir Louis Barnett in 1920 in a letter to the section of surgery of the Australasian medical congress which was being held at Brisbane; but the proposal was rejected. In 1924 Dr. William J. Mayo and the late Dr. Franklin Martin visited Australia and offered the fellowship of the American College of Surgeons to some of the leading Australians. When the newly elected fellows attended the next annual meeting of the American College they were impressed by the importance of its work, and on their return decided to revive the proposal to found a corresponding institution in Australia. After preliminary meetings a conference of delegates from the chief Australian States and from New Zealand was held in Sydney in August, 1926, and a provisional executive committee was elected which drew up a constitution for the new college. The first annual general meeting was held at Canberra in 1928 under the presidency of the Lord Stonehaven, the governor-general of Australia. Sir John Goodwin, F.R.C.S., the governor of Queensland, and Mr. Victor Bonney, who attended the meeting on behalf of the Royal College of Surgeons of England, were elected the first honorary fellows of the College. Sir George Syme was its first president; when he died in 1929 Sir Henry Newland was elected in his place, and it has recently been announced that Mr. R. B. Wade of Sydney has been elected to succeed him as third president.

The last years have seen a rapid growth. In 1930 the King granted the College permission to prefix Royal to its title and this was followed by a grant of arms. In 1931 it was decided to erect headquarters, and it was agreed that this should be situated in Melbourne. The building which has just been opened is free of debt and has been designed so that future extensions can be readily undertaken. It occupies a central position in Melbourne, standing near the University, while the Melbourne Hospital, the Children's Hospital, the Women's Hospital, St. Vincent's Hospital, and the Eye and Ear Hospital are in the same neighbourhood, and the Alfred Hospital, Prince Henry's Hospital, and Queen Victoria's Hospital may easily be reached by tram.

In 1931 and in 1934 the Australasian College coöperated with the Royal College of Surgeons of England in holding the primary fellowship examination of the English College in Australia, and it is hoped that examinations may be held in Australia and New Zealand at regular intervals. The friendly intercourse was continued when Mr. C. H. Fagge, on his visit in 1932, delivered the first George Adlington Syme oration and was made an honorary fellow. Last year Mr. Gordon Gordon-Taylor, who went to Melbourne as an examiner in anatomy for the primary fellowship examination, received a like honour.

As the possession of a senior surgical qualification is one of the requirements for the fellowship the College has been able to obtain uniformity in the regulations governing admission to senior surgical degrees of the Australian universities. A period of surgical apprenticeship is also an essential part of the training for the fellowship, and the College has therefore asked many of the large hospitals of Australia to create non-resident positions as assistants to indoor surgeons which are intended for men who have already been house surgeons and who wish to continue their surgical training with a view to becoming fellows. An agreement has been made with the Prince Henry's Hospital, Melbourne, whereby this hospital will function as a post-graduate school of surgery in collaboration with the College.

Application for admission to the fellowship of the College is made to the censor-in-chief who presides over two boards of censors, one in Australia and one in New Zealand. The censor-in-chief considers the qualifications of each applicant—a senior surgical qualification and a period of surgical apprenticeship are essential—and if he thinks fit asks the candidate to present himself to the appropriate board of censors for an oral examination. Fellowships with ophthalmology and laryngo-otology have been instituted and are governed by similar regulations. The original system of admission to the fellowship was somewhat different, and the revised system was introduced in 1934.

Soon after its formation the College founded a journal which has been published quarterly since 1928, at first under the title of the *Journal of the College of Surgeons of Australasia*, and since 1931 under the name of the *Australian and New Zealand Journal of Surgery*. The journal is edited by a committee under the chairmanship of Mr. H. B. Devine.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdrs. A. G. Bee to *Drake* for R.N.B., and A. Craig to *Pembroke* for R.N.B.

Surg. Lt.-Comdrs. H. J. McCann to *Victory* for R.N.B., J. A. Cusack to *Dorsetshire*, and A. R. Ewart to *Leander*.

ARMY MEDICAL SERVICES

Col. M. F. Grant, late R.A.M.C., having attained the age for retirement, is placed on ret. pay.

Lt.-Col. D. F. Mackenzie, D.S.O., from R.A.M.C., to be Col. (Col. Donald F. Mackenzie, D.S.O., on medical duty in the Aldershot Command, is 54, and has been in the R.A.M.C. since January, 1907.

ROYAL ARMY MEDICAL CORPS

Maj. A. Jackson to be Lt.-Col.

Capt. (*local* Maj.) J. C. Gilroy relinquishes the local rank of Maj. on ceasing to be empld. with the Trans-Jordan Frontier Force.

REGULAR ARMY RESERVE OF OFFICERS

Lt.-Col. F. B. Dalgliesh, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY

H. Dickie (late Offr. Cadet, Glasgow Univ. Contgt. (Inf. Unit), Sen. Div., O.T.C.) to be Lt.

D. R. Hood to be Lt.

Supernumerary for service with O.T.C.—Lt. F. L. Ker, supern. for serv. with Med. Unit, Edinburgh Univ. Contgt., Sen. Div., O.T.C., to be Capt. (Substituted for the notification in the Gazette of March 12th, 1935. *Vide* THE LANCET, March 23rd, p. 704.)

ROYAL AIR FORCE

The undermentioned Flight Lieutenants are promoted to the rank of Squadron Leader: A. F. Cook and E. Thompson.

Flight Lts. P. D. Barling to R.A.F. General Hospital, Hinaidi, Iraq; P. J. McNally to R.A.F. Institute of Pathology and Tropical Medicine, Halton.

INDIAN MEDICAL SERVICE

Lt.-Col. A. F. Hamilton, C.I.E., retires.

Major T. J. L. Thompson, M.C., R.A.M.C., has been appointed as officiating D.A.D.M.S., Eastern Command.

DEATHS IN THE SERVICES

The death occurred on March 25th, suddenly, at sea of Surg. Capt. Sidney Roach, R.N., retired, formerly medical officer of the Royal Naval College and Royal Hospital School at Greenwich. He qualified M.R.C.S. in 1897, having studied at St. Bartholomew's Hospital and took the D.T.M. & H. in 1921. He entered the Navy as a surgeon on May 25th, 1897. He served in the sloop *Alert* on the North American station, and at Bermuda naval hospital, and was promoted to staff surgeon in 1905, in which year he joined H.M.S. *Cambridge* at Devonport. Later he was medical officer of the R.M. garrison at Ascension of the cruiser *Indefatigable* in the West Indies; and of Chatham Barracks. During the war he was officer of the cruisers *Devonshire* and *Roxburgh* submarine depôtship *Bonaventure*. Then he the *Defiance*, torpedo schoolship at Devonport he entered the service of the Harrison Line, and board one of their vessels that he died. He home at Brading, Isle of Wight.

Lt.-Col. Francis George Adye-Curran died residence, Esker House, Rathmines, Dublin, on M at the age of nearly 90. Born in Dublin in 1845, and educated at Trinity College, he obta M.D. Dub. in 1867, became L.R.C.S.I. in the sa and F.R.C.S.I. in 1887. Early in life he joined t Medical Service and retired in 1893 with the Lieutenant-Colonel. He then engaged in private in Rathmines, Co. Dublin, and remained in pra to his final illness, being probably the oldest practitioner in Ireland. During the war he retu the Army although past 70 years of age at the ti served for a time in India. Col. Adye-Curran l for many years a director of the Apothecaries' Ireland, of which he was for a time governor; represented the Apothecaries' Hall on the General of Medical Education and Registration from 1905

CITY OF LONDON MATERNITY HOSPITAL.— the last year 1683 mothers were admitted in hospital and 210 were delivered in their homes. the exception of emergency cases sent in by officers antenatal supervision and treatment were where necessary, and postnatal clinic was arrang the care of the mothers when they left the ho The improvements which have been carried out duri year include the erection of a new operating th with adjoining sterilising room, but the hospital rec another £1000 a year if it is not to fall into debt.

KETTERING GENERAL HOSPITAL.—The increa the year's work at this hospital is the largest i last seven years, for the total number of cases, 2 exceeds those of 1933 by almost 7000, and is a double the number recorded for 1928. There wa excess of income over expenditure amounting to The total amount received from the hospital guild we contribution scheme was £7331, which was a rec The £10,000 appeal towards the cost of alterations and extensions is progressing satisfactorily. The daily average number of occupied beds was 76·25 as compared with 65·78 last year, and the average cost per patient (excluding out-patients) was £9 10*s*. 7½*d*., a decrease of 1*s*. 3½*d*. on the previous year.

PARLIAMENTARY INTELLIGENCE

OSTEOPATHS BILL

Select Committee's Inquiry

(Continued from p. 754)

THE Committee's inquiry continued on Friday, March 29th, and Monday, April 1st, with Lord AMULREE in the chair.

Sir William Jowitt Presents his Case

Sir W. JOWITT, K.C., principal counsel for the British Medical Association, addressed the Committee on their behalf. He said that the number of people in this country practising osteopathy and calling themselves osteopaths was estimated at between 2,000 or 3,000. Among them was a select body numbering 179 who stood in a somewhat different category. The hypothesis upon which the Bill was put forward was this: the unqualified osteopaths were doing some public harm, and it was therefore desirable that the present state of affairs should be brought to an end. The 179 qualified osteopaths were divided into two categories. Some 96 of that number were "old boys" of the British School of Osteopathy, and the other 83 had some American qualification. Of the 83, as far as the evidence went, roughly half were Americans and on the evidence American medical degrees were not accepted in this country. The proposal of the Bill was that all persons practising osteopathy to-day should come on to a register, subject to the point which Lord Elibank and the promoters would consider later as to how far subsection (iii) of Clause 6 (1) would involve examination.

WHERE THE BILL BREAKS DOWN

There might be occasions where it was necessary or desirable that the State should put upon a register persons who were not qualified, in spite of the manifest disadvantages of such a course. There might be compelling reasons such as those which operated in the cases of the dentists and the veterinary surgeons. The most important reason was the certainty that after the register had been set up everyone who went on the register would have to be properly and adequately qualified, there being in existence all the necessary schools and methods of teaching to secure that result. But was it certain that a corresponding advantage would be secured in the case of the osteopaths? Was it certain that from the moment the register was established everyone who practised osteopathy would be properly trained and properly qualified, so that the danger to the public which existed to-day would disappear? From that point of view he thought that the present Bill broke down altogether. The promoters were putting the cart before the horse. The Minister of Health had said that the first thing for the osteopaths to do was to get a proper school, and to set up a proper system of training. If they had done so they would have come before their lordships and said that they had a great deal of public support; they had a creditable school and hospital, and could claim that their system of education was comparable to that of the medical curriculum. In such circumstances their lordships might have said that they would permit a little wrong by putting unqualified people on to the register for the sake of the great good that would thereafter be achieved. But what would actually happen under this Bill? Dr. Kelman Macdonald had stated that there was no reputable school of Osteopathy in this country except the British School of Osteopathy. He (counsel) did not want to say much about this school, or about its dean, Dr. Littlejohn, but one thing at least was plain: it could not be regarded as in any way satisfactory, nor did he regard it as reputable. Dr. Littlejohn, he would say quite plainly, was not an honest man, and if there was to be a satisfactory educational system for osteopaths in the future, the less he had to do with it the better. If, on the other hand, there were more people like Dr. Macdonald, and it was possible to get some of them to give their time and attention to the school and develop a hospital in connexion with it, then he could imagine that their Lordships might approach this Bill from a different point of view. It was significant that Dr. Macdonald and his Association had never recognised the students of the British School of Osteopathy, and he hoped they never would. But in those circumstances to come to Parliament and ask the State to recognise that which Dr. Macdonald would *not recognise*, knowing that the only prospect of osteopaths being educated in the future was through the British School of Osteopathy, was to ask something which was quite impossible.

No one doubted that there were many cases in which osteopathy was very valuable, but the claim put forward in the Bill was a very wide claim. Parliament was asked to allow people to be put on the register to treat all diseases. Not one single witness had been called who treated acute diseases. There was no evidence that any osteopath in England treated acute diseases. Mr. Streeter and Dr. Macdonald had what they described as office practice. If they were going to say that the State recognised osteopaths as fit to treat these diseases, why should they hesitate to say that they should be able to sign death certificates? The reason why a medical man could treat diseases better than a layman was because he knew something about diagnosis.

NON-SECTARIAN TRAINING

The function of education, continued Sir William, was to enable a man to think for himself, and it was a mistake to start the student from a prejudiced point of view by indicating to him that he was never going to use drugs. The doctor had both a professional and a financial interest in getting a reputation for curing his patients, and if this osteopathic theory was right, why did the doctors not accept it? They understood it. The young men coming from the universities and medical schools to-day were in a position to judge. The right solution was to let these people take their medical degrees, and afterwards carry on their researches in any way that they liked, as they were perfectly entitled to do; the British Medical Association would deplore any ostracism of a man like Dr. Kelman Macdonald. The Bill if passed, Sir William concluded, might do a grave public injury by duplicating machinery and setting up a second register. Wherever this happened the tendency was for the lower qualification to be taken, and at a time when medical education ought to be improving they would deliver it a blow and send it backward.

Sir Henry Brackenbury's Evidence

Sir HENRY BRACKENBURY, vice-president of the B.M.A. and a member of the General Medical Council, next gave evidence. Examined by Sir WILLIAM JOWITT, he said there was now a movement by the Council to place the whole of general biology in the pre-medical stage, so that the real five years' education would begin after the student had taken physics, chemistry and biology. Replying to the CHAIRMAN, he said that from the time of the ordinary matriculation examination it took a student two years to prepare for the five years' medical course.

COUNSEL: There is plenty of scope for a man to continue to learn after his name has been placed on the Register?—WITNESS: He must do that, otherwise he will be not merely a scientific failure, but a financial failure too.

COUNSEL: A man like Dr. Kelman Macdonald can practise osteopathy?—WITNESS: He can practise anything he likes.

COLLABORATION WITH OSTEOPATHS

COUNSEL: Would you have the slightest hesitation in consulting or using a man like Dr. Kelman Macdonald?—WITNESS: No; not in the least.

Lord ELIBANK: Does that apply to all your profession?

—WITNESS: There would be no feeling against consulting Dr. Macdonald because he was practising as an osteopath. That is to say, being on the Medical Register there could be no question about the appropriateness of any medical practitioner consulting him if he wished to do so. There is this distinction against general consultation with a person on the Medical Register who is practising osteopathy, as there is with persons who are practising homœopathy—that if I wish a consultation with a colleague the value of that consultation is likely to be less if I know beforehand that he has adopted a fixed and restricted method of looking at things.

Later Lord ELIBANK asked: Have you yourself ever used an osteopath or invited the coöperation of an osteopath in any of your cases?—WITNESS: Probably in the sense in which you mean it, no. I have had a number of patients who have expressed a desire to see an osteopath about certain conditions and I have never placed the slightest obstacle in their way.

Lord ELIBANK: You have not advised them not to go?—WITNESS: Never.

Replying to a question about Dr. Macdonald's complaint of his difficulty in obtaining an autogenous vaccine in Edinburgh, Sir Henry Brackenbury said: "In that case Dr. Macdonald was treated very badly, and in a way he should not have been treated." No medical man was obliged to associate himself with or consult with any other medical man if he did not wish to do so, but if the conduct complained of had been brought before the British Medical Association they would have said to the person concerned, "You acted very impolitely and very improperly."

Lord ELIBANK asked why Dr. Axham was struck off the Register for acting as anæsthetist to an osteopath, when at the present day a doctor could coöperate with an osteopath without coming to any harm.

The Witness, after explaining that Dr. Macdonald was a registered medical practitioner, pointed out that what the General Medical Council was anxious to do was to prevent "covering." If, habitually, a registered medical practitioner helped an unqualified and unregistered practitioner to carry on his practice by just coming in to help him to do those things which the State said must only be done by a registered medical practitioner, then he was liable to be called up and judged for an offence. The offence was that of enabling an unqualified person to carry on his practice as though he were a registered person.

Continuing his evidence the witness mentioned that there were a number of general practitioners who practised manipulative surgery in the colliery areas. Replying to Lord ELIBANK, he said that these practitioners learned manipulative surgery in the medical schools, but their skill in the art developed with the experience they had in daily practice.

Lord ELIBANK: Is the subject in the curriculum of the medical schools?—WITNESS: It is compulsory. It has been emphasised very much since the General Medical Council made its last revision of the medical curriculum in 1926. Since then the emphasis placed on the teaching of manipulative surgery has been very much increased.

The witness went on to speak of the great difficulty of differentiating between major and minor surgery, and said that if any attempt was made to bring in a class of persons who might practice minor surgery, but not major surgery, it would be necessary to have a tribunal constantly sitting to say whether a man had or had not exceeded the powers given to him. Speaking of the wide general knowledge required for making a correct diagnosis, he said that the diagnosis spoken of did not seem to cover the same thing in the two cases. It seemed to him, as he had listened to the evidence, that the osteopath's diagnosis was merely directed to the location of a special osteopathic lesion. The osteopath's point was not whether a person had bronchitis, or pneumonia, or gall-stones, or appendicitis, but whether the basic cause of his disease was in the second or seventh dorsal vertebra. The doctor's diagnosis might or might not have something to do with the spinal column, but it was directed to form an exact a picture as possible as to what was going on in the patient's body.

A VOLUNTARY REGISTER.

The witness referred to the Chartered Society of Masseurs as having a voluntary register which was widely recognised both by the profession and the public. This was a very good example of a voluntary register. A registered masseur or a masseuse could not treat a patient without going through a doctor. That was because massage otherwise might be entirely misdirected. Masseurs did not regard themselves as competent to diagnose cases in which massage was the correct treatment. When a skilled person had decided that massage was the right form of treatment, then the masseur was the right person to give that treatment.

THE AMERICAN PARALLEL

In answer to further questions by COUNSEL, the witness said that if the situation were the same as it is in the United States the B.M.A. would withdraw its opposition; the Bill would be a necessary thing. In the U.S.A. no one was allowed to practise the healing art unless he was on a register recognised by the State. The English system, on the other hand, was to have one recognised minimum qualification, and allow anybody else to practise as they pleased. He thought there were probably 25,000 unregistered persons in this country who in some form or at some time were in fact practising. But in these circumstances State recognition involved the picking out from among all the cults one or more for registration.

"It seems to me," said Sir Henry, "that we must either have a British system of complete liberty for the public and for those who wish to practise any healing art—with State recognition on one minimum qualification only—or we must adopt fully and completely the American system of prohibiting the practice of healing by anyone who is not on a State register. Then you must have a number of State registers in order that the public may be able to exercise their choice . . . As soon as under that system the State recognises one or more forms of healing it is bound, I think, to place those forms of healing at the disposal of the public in any State arrangements that it makes for dealing with public health . . . The chaos—I do not think I am putting it too high—that would be caused in public health administration by the recognition of more than one register under the English system would be so great as to be almost impossible."

The WITNESS then described the position in the United States and Canada as he had studied it on a visit to those countries. In the U.S.A. there were 142,000 trained medical practitioners and 36,000 others, namely, 7680 osteopaths, 16,000 chiropractors, 2500 naturopaths and 10,000 Christian Scientists. These figures were taken from the report of a committee partly governmental and partly representing the American Medical Association. There were a bewildering number of differences between the arrangements made in the various States. Thus, 8 States of the Union gave osteopaths a limited right to use certain drugs, whereas in 17 they might not use drugs without special licences for individual cases.

COUNSEL then referred the witness to a publication, No. 16 of the Committee on the Costs of Medical Care, by Louis S. Reed, Ph.D., in which the following passage occurred: "In point of numbers the growth of osteopathy has practically stopped. The failure to grow is probably due for the most part to two things—chiropractics and evolution of osteopathy." The report, the witness said, was published a year or just over a year ago. As the result of investigations from year to year regarding the number of osteopaths practising in the United States, it was shown that for the last few years they had been to all intents and purposes stationary.

Lord ESHER: Have you deduced anything from the decline of osteopathy in the United States?—WITNESS: The best osteopaths have approached so near to the medical standard that those who wish to go in for that form of healing take the whole medical course rather than take something which costs them nearly as much and takes nearly as long, whilst they find themselves having taken the full Medical Course with a greater status . . . . . . With regard to those who are not so scientific and earnest—and I think I include the majority—the tendency has been rather to go over wholesale to the chiropractors' field, because they can do the thing much more cheaply in a shorter time, and they can hold out all sorts of wild promises of cure which the best of the osteopaths would not feel themselves able to do.

DIFFICULTIES IN THIS COUNTRY

Sir W. JOWITT, having resumed his questioning on the attitude of the B.M.A., the witness said that if they were to consider the economics of the proposed registration, he would say that the medical profession would probably benefit from it rather than otherwise. The opposition was not influenced by any feeling that the Bill was going to harm the medical profession.

COUNSEL: You do not oppose as such the compilation of a register?—WITNESS: Not at all. It would be useful and would enable the public to distinguish between those who had a training and those who had not.

The witness added that a State recognition involved something in this country which was quite different from the existing State register in the United States. We had to start here with the knowledge that anybody may practise healing without doing anything illegal at all, provided he did not pretend to be a registered medical practitioner. There was no necessity here for a register, for a State recognition in order to supply a public demand. On the other hand, if the State chose to pick out one or more particular cults for State recognition, that involved in this country a responsibility and consequences which were quite different from the necessary registration of the various schools of thought in America. It involved the giving of a cachet or authority to theories and beliefs which were unaccepted by almost the whole scientific world. There was a very considerable section of the public who thought that the stamp on patent medicines was a State guarantee that the medicine would do all that was claimed for it.

In answer to Counsel's questions, the witness said that, as far as the increasing recognition of the importance of manipulation and the increasing recognition of the limitation of drugs were concerned, he would like to give the osteopaths every credit for having emphasised those points. They were not new points, because the evils of indiscriminate drugging, and the value of surgical manipulation had been acknowledged and practised in medicine before the time of Still.

COUNSEL: You pay a high tribute to manipulative surgery, but it is to the extent of the claims that the osteopaths are making that you now raise your objection?—WITNESS: Yes, entirely. They are asking recognition over the whole field of medicine.

State recognition, he added, would involve the use of registered persons for State purposes—for poor law, national insurance, infantile welfare and school-children.

Lord ESHER: There would be no objection to that if the basic principle of osteopathy was true?—WITNESS: If the basic principle was true there would be no other register but the osteopathic register, as the Medical Register would be wiped out.

A QUESTION OF BIAS

The Witness said the four years' osteopath's course would compare with a six years' medical course, or the five years' course would correspond with a seven years' medical course. From the beginning, moreover, there was a bias in the minds of the students.

CHAIRMAN: Is not the medical education biased?—WITNESS: No. It is unbiased in so far as it teaches the basic facts of the science of medicine. You can say that those who conceive the world to be round are biased as against those who believe the world to be flat, but I do not think you can take the belief that the world is round to be a biased belief.

Lord ESHER: That is only because you believe it to be true.

The witness did not think that the establishment of an osteopathic register could profitably lead to personal collaboration in general between osteopaths and registered medical practitioners. Indeed, the effect would be all the other way. He would know, as a medical man, that any one whose name was on the osteopath's register had had from the beginning a biased education, and had established in his mind certain fixed ideas.

Lord ELIBANK: Have you no fixed ideas on medical science or treatment?—WITNESS: No, except in the sense that if a fact seems to be established I should accept it for the whole or almost the whole of the scientific world. I should hold it to be the right of any man on the Medical Register to take any view he likes.

Lord ELIBANK: You say there is no probability of collaboration between the osteopath and the medical profession under this Bill, and you say the osteopaths are doing good work in the community?—WITNESS: A number of them in a limited field.

Lord ELIBANK: Can you help the promoters of the Bill by telling me how we can bring about that collaboration which I want and from what I gather you want too?—WITNESS: In my belief this Bill will not lead in that direction but in the opposite direction. At present I, as a medical man, have my liberty without transgressing any medical law or rule of the General Medical Council to consult with and use any one in the world that I can with reference to the welfare of my patients, so that there is nothing to prevent any collaboration between myself and an osteopath or anybody else.

Sir Henry Brackenbury Cross-examined

Mr. MURPHY, counsel for the promoters of the Bill, questioned Sir HENRY BRACKENBURY about the authenticity of the figures relating to the United States which had been spoken to by the witness. Sir Henry said he did not think that there was Government responsibility for the publication which had been quoted but the Government had representatives on the Committee. Council suggested that the book was simply a publication of an individual member of the Committee expressing his own views. The witness disagreed. He did not think the author (Dr. Reed) was a member of the Committee, but he took it that in accordance with the procedure indicated the report had been submitted in its final form to each member in order that he might express his dissent for it if he desired to do so. No such dissent was expressed.

COUNSEL: You tell me that, and of course I accept it as your view, but I suggest to you that there is nothing in this publication from beginning to end to show that it has received the approval of the committee.—WITNESS: I have never claimed that it has.

One of the reasons given for a lack of increase in the number of osteopaths in America, Sir Henry agreed, was the rise in osteopathic standards. This rise had been brought about in a number of States according to the writer of the book, by State action. But except in those nine States which had recently enacted Basic Licence Laws, there was no legislation involving the raising of the standard of osteopathic education. The standard education had been raised by the action of the osteopaths themselves.

COUNSEL: Will you take the view that there being a large number of persons practising osteopathy in this country it is highly probable at least that if certain definite standards and qualifications are insisted upon and enforced you might find a smaller number practising osteopathy, but a much better qualified number of persons?—WITNESS: Yes.

COUNSEL: That is not merely highly probable but almost inevitable?—WITNESS: One of the results.

The Witness said the B.M.A. possessed figures which reached the conclusion stated by a witness last week that osteopathy was dying in the country of its birth. The figures indicated a stoppage of the increase. He promised to let the Committee have the figures.

The Witness said he was satisfied to leave things as they were in this country, even at the risk of people resorting to persons who were not qualified. He preferred the English system to the American system. He did not think it was an undue risk to retain the present liberty.

COÖPERATION AND COVERING

On the question of coöperation with osteopaths, Sir Henry reiterated his belief that such coöperation would be futile.

Lord Elibank: Dr. Macdonald has medical training and has since become an osteopath. Does that mean that he has adopted a fixed idea, and how can you reconcile what you say about coöperation ?—Witness: As far as I am concerned that objection would hold with Dr. Macdonald. I can conceive of a number of cases under my responsibility in which I might have Dr. Macdonald to do manipulation, but knowing that Dr. Macdonald has adopted certain fixed ideas this would weigh with me in deciding whether coöperation with Dr. Macdonald would be valuable.

Counsel: You have not the same confidence in Dr. Macdonald because he has studied osteopathy ?—Witness: Dr. Macdonald has a perfect right to adopt any view. He is very likely right and I am very likely wrong, but if I believe that the principles on which he acts are not true that prevents useful coöperation between him and me.

Later Counsel said: The osteopath whom you believe to be performing a certain useful function could require somebody occasionally to administer an anæsthetic. If a doctor administers an anæsthetic for an osteopath and complaint is made to the General Medical Council the matter is taken up and that medical man is in considerable jeopardy ?—Witness: That case has to be dealt with on its merits by the General Medical Council. He is in some jeopardy.

Counsel: Although he has only assisted a man in doing something which, having regard to the principles of English liberty, he is perfectly entitled to do ?—Witness: No; that is not quite right. You must not ask me to prejudge cases which, as a member of the General Medical Council, I may have brought before me . . . . I have no doubt that if a registered medical practitioner accepted a salary from an osteopath to give an anæsthetic for an unregistered osteopath, the liability being habitually to administer anæsthetics, there would be a serious liability that that person would be put off the Register. As things stand at present the medical practitioner who gives an anæsthetic knows that his name may come before the Council and be erased from the Register.

Counsel: If an anæsthetic is administered at all it is desirable that it should be done by a medical practitioner ? —Witness: Fortunately that is one of the theories regarding which the public has shown sense.

Counsel: A registered medical practitioner giving an anæsthetic for the purpose of enabling an osteopath to carry out a useful piece of healing may find himself in considerable jeopardy ? Witness: Yes, but I should like to qualify that. The only reason would be if by so doing he was enabling an osteopath to treat patients as though he were a medical practitioner. If the charge were not proved up to that point he would be in no jeopardy. . . . .

Lord Elibank: If the medical practitioner wants to give anæsthetics regularly he would come within the rule ?—Witness: He might and he might not. The charge has to be that the registered medical practitioner is assisting an unregistered person to treat patients as though he were a registered medical practitioner. It depends on the Council whether that charge is held to be proved or not.

Counsel suggested that, in view of the difficulty of knowing what might be the consequences, the vast majority of medical practitioners would be on the safe side and not administer the anæsthetic for an osteopath. To which the witness replied that the vast majority of medical practitioners never had been and never would be asked to do so.

After questions about the theory underlying the practice of osteopathy, Counsel quoted the witness as saying he would not regard belief in the roundness of the earth as a bias. Assuming for the purpose of the question that the round-earthers were the medical profession and the flat-earthers were the osteopaths, he suggested that it would be unreasonable and useless to ask a flat-earther to spend six or seven years in an educational establishment of round earthers before going to an educational establishment of his own. The witness said that no man with a fixed idea could get it removed unless he had some sort of scientific education.

Further Questions to Sir Henry

Mr. Dickens (Counsel for the B.M.A.) then put a number of questions. In the course of his replies the witness said he would not hold it improper for him to give an anæsthetic for an unqualified person if the responsibility for the case remained with himself or any other registered practitioner.

TWO STATE REGISTERS

In describing the disadvantages which would attend the setting up of two State registers in this country, the witness instanced the difficulty of establishing a criterion of incapacity for work under National Health Insurance, owing to the fact that there would be two different bodies of people looking at such questions from a different angle. Then, again, if it was claimed that osteopaths by manipulating the spine could prevent or greatly minimise the incidence of puerperal sepsis and eclampsia, it would be a wicked thing to deprive women of the opportunity of having their spine manipulated by osteopaths. That would mean that they would need to establish maternity and child welfare centres not merely for scientific medicine but also for osteopathy. The same would apply to the care of the health of school-children. If it was claimed, as it had been claimed, that the reduction of osteopathic lesions would prevent the incidence of infectious disease in the small child, clearly such children ought to have their spines examined and their osteopathic lesions rectified before going to school, or while at school, in order that the incidence of measles and other infectious diseases might be diminished.

If that was true, and the public desired to have safety in that way, there would have to be an alternative system of medical inspection and treatment provided by the State in every State department of medical activity. It seemed to him also that the local authorities would have to provide one or the other, even if they did not provide both, sets of medical officers of health. It might become a burning question at local municipal elections as to whether they should have disease prevented by the manipulation of the spine or by scientific medical methods.

OSTEOPATHIC THEORY: TRUE OR FALSE

Lord Esher: You said in your evidence that the osteopathic theory had been repudiated by the scientific world, but Dr. Macdonald said that he had made genuine efforts to get the scientific world to examine the theory. Is it the habit of the scientific world to repudiate evidence that it has not examined ?

The witness said he disputed Dr. Macdonald's statement, but he would rather leave that to the scientific witnesses. It seemed to him inconceivable that the anatomists and physiologists who have been working for 100 years investigating the structural and functional states of the body should have failed to observe the osteopathic lesion.

Lord Redesdale: Medical students are taught to keep an open mind ?—Yes.

Is it not the case that the medical profession are aware that to a certain extent they are still groping in the dark ? —Yes, in a great many instances.

You are not advancing the inconvenience to the State as an argument against the recognition of a new method for the prevention of disease?—Not if it has been scientifically proved.

CHAIRMAN: Might both theories be true—the medical and the osteopathic theory?—Oh, no.

If the one is true, the other is false?—Yes. I am dealing with the theory of osteopathy.

In certain cases you agree osteopathy does good work, but you take the view that it is limited?—Yes.

What kind of work do you confine it to?—The sphere of manipulative surgery, mainly dislocations or structural abnormalities of the joints.

The witness added that he had found that in most cases where osteopathic treatment was called for it was some trouble of the knee or elbow-joint, and those cases had occasionally been put right. There might be structural abnormalities of the joints of the spine in which manipulative surgery would be the right kind of treatment, but such were not within his own experience.

Protest from Chiropractors

Mr. ST. JOHN RAIKES, counsel for the British Chiropractors' Association, at this stage asked permission to make a statement regarding the evidence of Sir Farquhar Buzzard who quoted from an American book, the statement that chiropractic treatment was an old form of faith cure under a new name. As the chiropractors might be done harm in the eyes of the public by such statements, he wished to say that they took very strong exception to the statement. Chiropractics had nothing to do with faith curing whatever.

Dr. Mennell's Evidence

Dr. JAMES MENNELL, medical officer in charge of the physiotherapy department of St. Thomas's Hospital, London, then gave evidence for the B.M.A. Replying to Mr. Dickens, counsel for the Association, he said he started upon the system of joint manipulation in 1907, and since that time had been gradually elaborating many other manipulative methods of treatment. He had set out the results and the technique in several text-books, one of which, entitled "Backache," had been described to the Committee as an osteopathic text-book. In reviewing the immensely wide field covered by the practice of manipulation, he mentioned incidentally a kind of asthma in which there was reflex irritation of the nerves from spinal trouble, and which could definitely be relieved and even cured by manipulation. Manipulative methods, however, were not of any use in acute diseases, so far as he knew.

COUNSEL: Have you ever had a success which required the pre-supposition of anything like the osteopathic theory?—WITNESS: None.

Upon being reminded that Dr. Macdonald had said that his text-book was inspired by osteopathic teaching, the witness traced his introduction to manipulative treatment to the inspiration of one of the surgeons at St. Thomas's who took him over to Paris. He came home very much interested in work being done there, and he was given the opportunity to investigate at St. Thomas's Hospital, where he held an appointment for two years. Then he began to consider seriously specialising in physical medicine. As a result his first visit to the United States was made in 1919, 12 years after he had began to be interested in the subject. At that time he had never read an osteopathic paper or text-book, or seen any osteopathic work. Yet in 1919 he was invited to address on the subject of manipulation one of the most august medical bodies in the world—the Association of American Surgeons. With regard to text-books, Dr. Mennell admitted that he had read and very carefully studied one which was entitled "Osteopathic Mechanics." That dealt with the mechanical side with practically no theory at all. He had been practising joint manipulation, or manipulation of some sort, for 30 years, and probably he should have been a very easy convert to the osteopathy, but he found it easier to accept the orthodox explanation than the osteopathic explanation. They were asked to investigate and prove the osteopathic theory and the osteopathic treatment. He asked that those two things should be separated. To say that no one had investigated treatment was a little hard on one who had spent 30 years in endeavouring to do that very thing. As to the theory, so far as he could make it out, and as far as his reason would allow him to go, it seemed to him that it must be a creed, and as such it was incapable of scientific investigation. No one could believe it scientifically.

COUNSEL: Supposing the manipulative methods are confined to what you say are their legitimate objects—namely, local troubles—are they a danger unless the practitioner is very highly skilled?—WITNESS: Very great. There are physical dangers. The standard attained must be absolutely the highest.

Asked whether it was necessary for an osteopathic student to study all the subjects studied by a medical student, the witness said that any medical man who wished to practise any specialty had to take an elementary training in all branches of medicine and surgery. His own practice had been confined to physical medicine, but he was truly thankful that he had himself done so; he knew enough to tell his patient when to go to some other practitioner for help. A man who specialised ought to have adequate knowledge to know when he was himself ignorant.

Cross-examination of Dr. Mennell

Mr. THORPE, K.C., leading counsel for the promoters, asked the witness if he thought that qualified osteopaths performed useful service in this country? Dr. Mennell replied that they had helped many of their patients.

COUNSEL: How is it they do good? Is it by accident?—WITNESS: May we take some concrete case. Would you like the case of asthma? There are undoubtedly cases in which the qualified osteopath would bring health, comfort, relief, and possibly cure in suitable cases But if asked to deal with such a case I hope that I should investigate and find out whether it came under the heading of a suitable type for that treatment.

Does it come to this, that there are certain types of cases in which properly qualified osteopaths can bring benefit?—Yes.

And conversely there are certain cases which you could elaborate which they ought not to be allowed to deal with, such as pneumonia and so on?—Yes.

Later COUNSEL asked: What is the fundamental distinction between you and the osteopaths?—WITNESS: I cannot accept that the osteopathic spinal lesion is the most important single factor in the production of disease and the most important curative factor when the disease is attacked.

PASSAGES FROM A PRIVATE LETTER

COUNSEL: There was a time when you thought something of Dr. Andrew Still. Did not you refer to him, writing to one of his pupils, as your great master?—WITNESS: He was a very remarkable, inspiring teacher.

COUNSEL asked if the witness remembered saying: "In my own mind and in my own heart I pay loyal tribute to the great man who first conceived the possibility of applying manipulative treatment to the joints of the spine."

The witness replied in the negative, but when shown the signature of a letter to America dated August 6th, 1931, produced, he admitted that it was his own signature.

COUNSEL: Do I read this aright? You were referring to the orthodox medical people of this country and did you say this: "You mention one of my illustrations and add that this is the only place where apparent credit is carried to osteopathy. This is true, and I am sorry to say, deliberate, in spite of the fact that I know quite well of the truth of your statement that every figure and every page is a corroboration of the teaching of Dr. Andrew Taylor Still."—WITNESS: I did, but I believe there is *nothing in that to imply that I accepted the creed.*

COUNSEL: Having said that, you go on: "but you must remember that I was writing in the hopes that I might appeal to the medical men of this country and of the U.S.A. to whom the word 'osteopathy' or 'osteopathic manipulation' is anathema." Is that why you did not pay an open tribute to osteopathy—because it was anathema to medical men in this country?—WITNESS: No. We are against the eternal problem when you connect the manipulation with the creed.

COUNSEL: You go on "For them the very word must be dropped" (that is osteopathy) "and equally for them *the teaching of your great master (Dr. Andrew Still)* must be doled out in minute doses and in a disguised form, otherwise prejudice will be so great that again the progress we have already made will be set back for another generation." *What do you mean by that?—WITNESS: It is* the attachment of their treatment to their faith that has already thrown back the whole thing.

COUNSEL (reading): "In my own mind and in my own heart I pay loyal tribute to the great man who first conceived the possibility of applying manipulative treatment to the joints of the spine." Is that true?—WITNESS: Yes.

The witness added he was still willing to pay tribute to Dr. Still as a remarkable man, and a great teacher. Medicine was international in its character.

COUNSEL: You go on to say "I am wise to insist on what one may call the ABC of treatment first before making any attempt to enter into the wider realms."—WITNESS: I suppose I was referring to the wider realms of details.

COUNSEL: Are not the wider realms the theory of osteopathy? Details are not the wider realms?—WITNESS: I think so.

Proceeding, the witness protested that the letter was confidential. COUNSEL quoted further: "I hope that you will consider the views that I have expressed here as confidential, as were they broadcast I am afraid that my first effort to accustom my professional brethren to the idea that manipulative treatment has its useful place would be seriously handicapped."

COUNSEL: You found it difficult to get your brethren to accept manipulation?—WITNESS: In the early stages, but not now.

COUNSEL (again quoting): "So far the great point gained is that I have been able to produce an osteopathic text-book, however rudimentary, which has received appreciative notice in every medical journal."

That, COUNSEL suggested, was meant to bring into the heart of the osteopath to whom the witness had written that someone was blazing the lone trail in this unhappy country. He quoted further: "The attitude that I have always adopted is that orthodox medicine in which I was trained, has a useful and invaluable purpose to serve, but that the less orthodox methods have no less their own sphere of usefulness, and that until the two are combined they will neither of them rise to perfection, and that therefore neither of them will serve their fullest purpose."

The witness said that was his opinion and true belief, that when the osteopath is combined with the medical practitioner we should have a much more valuable article than either of them separately.

Further Questions to Dr. Mennell

Re-examined by Sir WM. JOWITT, counsel for the B.M.A., the witness said that so far as the theory of osteopathy was concerned he could not accept it. If the theory were right manipulative treatment would be the right method of dealing with all diseases, whereas in some diseases it would be extremely dangerous. No medical man was justified in prescribing a treatment unless he had good, solid scientific reasons for prescribing it. Manipulation came under that heading. His work had been to establish manipulative work on a solid foundation.

Lord ELIBANK *asked whether if osteopathic* manipulation was based on scientific thought and observation it was not entitled to the same recognition as the witness's manipulative treatment received. The witness replied: "Not while attached to a creed which is *not susceptible to scientific proof or disproof.*"

Before the courts adjourned the witness, addressing the Chairman, said he was frankly disturbed about the letter that had been read. It was undoubtedly written in entire confidence to a man who presumably had written to him in very friendly terms. He thought one was privileged in a private and confidential communication to speak with absolute freedom. The CHAIRMAN said he understood, and thanked Dr. Mennell for his assistance.

NOTES ON CURRENT TOPICS

Medical Qualifications in India

IN *the House of Commons on March 28th the* Government of India Bill was further considered in Committee. Mr. MOLSON moved an amendment to Clause 118 (Professional qualifications in general) with the object of preventing persons with European professional qualifications being disqualified from practising their professions in India. His amendment, he said, sought to do three things. In the first place it sought to restrict the protection to what he might call vested interests by defining more precisely those whom it was intended to protect. Secondly, the amendment extended protection to those who began to engage in a profession during the time that would elapse between the passing of this Bill and the passing of an Act of the Indian Legislature prescribing those qualifications. Thirdly, his amendment sought to make the previous sanction of the Governor necessary before any such new qualifications took effect. Nothing in this amendment was doing anything to force European professional men upon India; it did not endeavour to compel Indians to employ people with European qualifications, but only to prevent people with European qualifications from being disqualified from practising professionally in India.—Sir T. INSKIP (Attorney-General) said that the Government were prepared to accept the first two parts of the amendment, but not the third.

On Clause 119 (Medical qualifications) Sir T. INSKIP moved the first of a series of amendments to restrict the clause to British India, because he explained that the arrangements dealt with concerned only British India, and not the India including the States.—Sir F. FREMANTLE asked if there was no arrangement by which later on this might be extended to Federal India.—Sir S. HOARE replied that they must deal at present with British India. The whole basis of this clause was reciprocity between the medical councils of Great Britain and of India. There was no medical council for the Indian States. There was, however, no reason in the future why the Indian States should not accede to this part of the Act when they so wished, but for the moment they dealt only with the two medical councils.

Paying Patients in Voluntary Hospitals

In the House of Lords, on April 2nd, Lord LUKE moved the second reading of the Voluntary Hospitals (Paying Patients) Bill, which enables hospitals to provide accommodation for pay beds. Such beds, the noble lord said, were not to be provided at the expense of or by reduction in the number of ordinary beds. Patients in the pay-beds would be those whom a hospital almoner would not usually accept in the ordinary wards, but who could not afford the cost of private treatment in their homes and urgently required the assistance of a hospital with all its specialist treatment. Such patients were not the very poor, but the comparatively poor, who had sometimes been called "the black-coated poor." The provision of pay-beds in recent years had become recognised as a customary part of the function of voluntary hospitals. The *raison d'être* of the Bill was that some hospitals, in order to provide pay-beds, had recently obtained private Acts, and others wishing to do so must adopt the same procedure, which would cost at least £500. The present Bill would provide a uniform method of removing such anomalies, while safeguarding the interests of the sick poor. The Bill embodied the considered views of the King Edward Hospital Fund and the Hospitals Association.

Lord SANDERSON said that the Opposition had certain misgivings about the Bill. They were very anxious that it should not be the means of cutting down the services for poor people who could not afford to pay. They did not want the waiting lists in the hospitals to become longer or to run the risk of hospital treatment being cut short because of the pressure of the waiting list. The Opposition were very dissatisfied with the hospital system, or lack of system, and wanted to see all the hospitals taken over by the municipalities, publicly controlled, and kept open for free treatment for all who needed it. They should be supported out of the rates.

The Earl of DUDLEY, speaking as chairman of one of the large voluntary hospitals in London, supported the Bill. He said he hoped that it would not interfere with the powers of committees of management to charge varying fees in hospitals where they had the power to charge for in-patients. He had heard it said that it was the intention of the Charity Commissioners to issue an order limiting the amount to be charged to seven guineas. That would be a hardship on the lower-paying beds. In the hospital which he controlled they were able to charge as high as ten guineas for single rooms, but if they were to limit their charges to seven guineas they would have to raise the fees of the lower-charged beds, because the ten-guinea beds naturally covered to a large extent the charges made for the beds of lower cost.

Viscount HAILSHAM, Secretary of State for War, said that Lord Luke had made out a case for the desirability of having some beds available for that class of persons who were willing to make some payment towards the necessary expenses of receiving treatment, but were unable to pay the fees of a nursing home. The Government had considered the point made by Lord Sanderson, and had come to the conclusion that it was right to provide pay-bed accommodation, but that safeguards should be insisted on to ensure two things—first, that the property and funds of a hospital settled on it for the benefit of the sick poor were protected and prevented from being diverted for any other purpose; and secondly, that the accommodation which would otherwise be available in the hospital should not be restricted, and that there should be no risk of preventing poor people from having the amount of accommodation which would otherwise be available for them. While the Government would support the second reading of the Bill, they would feel it their duty to move amendments proposing specific safeguards with regard to the funds and property of the hospitals and dealing with other matters. He did not agree with Lord Sanderson's preference for a municipal rather than a voluntary system.

The Bill was read a second time.

Royal Assent

Among the measures which were given the Royal Assent by Commission in the House of Lords on Thursday, March 28th, were the following Acts: Ministry of Health Provisional Order Confirmation (County of Holland Joint Hospital District) Act, 1935; Ministry of Health Provisional Order Confirmation (Guisborough Joint Small-pox Hospital District) Act, 1935; Ministry of Health Provisional Order Confirmation (Huntingdonshire Joint Hospital District) Act, 1935; Ministry of Health Provisional Order Confirmation (South Chilterns Joint Small-pox Hospital District) Act, 1935.

HOUSE OF COMMONS

WEDNESDAY, MARCH 27TH

Medical Men and the Speed Limit

Mr. GLOSSOP asked the Home Secretary if he would instruct the police that doctors on their way to attend urgent cases were not to be prosecuted for exceeding the 30 miles per hour speed limit; and whether the same exemption would be granted to veterinary surgeons.—Sir J. GILMOUR replied: The question whether there should be an exemption from the speed limit in the case of vehicles used by members of the medical profession when attending urgent cases was discussed when the Road Traffic Act, 1934, was passing through Parliament, but it was decided that it would not be practicable to allow this exemption. It would be equally impracticable to place on the police the responsibility for assessing the degree of urgency when considering the question of instituting proceedings, and in my view the only satisfactory solution is to leave the matter to the courts.

THURSDAY, MARCH 28TH

Unemployment Assistance Expenditure

Mr. D. G. SOMERVILLE asked the Minister of Labour the present average weekly expenditure of the Unemployment Assistance Board; and by what amount, if any, this exceeded the anticipated average.—Mr. STANLEY replied: The present expenditure on unemployment assistance allowances is at the rate of about £44,000,000 a year. This accords substantially with the anticipated expenditure, as stated in the Financial Memorandum to the Unemployment Assistance (Temporary Provisions) Act.

Medical Rejections of Police Recruits

Sir WILLIAM JENKINS asked the Home Secretary (1) what was the percentage of men rejected on medical grounds who applied to join the police forces in England and Wales for the years 1932, 1933, and 1934; and (2) what number of applications was received to join the Metropolitan police force in 1933, 1934, and to the latest available date in 1935: what was the percentage of men rejected on medical grounds; and what percentage for causes other than medical.—Sir JOHN GILMOUR replied: The following statement gives the figures relating to the Metropolitan police. I regret that I have not got corresponding information for the county and borough forces.

—	1933.	1934.	Jan. 1st, 1935, to March 23rd, 1935.
Completed application forms received	8027	5893	1373
Rejected as below standard..	70 %	51 %	42 %
Attended for examination ..	1682	2415	724
Rejected on medical grounds	46 %	47 %	54 %
Rejected on other grounds ..	20 %	19 %	16 %

Milk and Infectious Disease

Sir ARNOLD WILSON asked the Minister of Health whether he would draw the attention of medical officers of health to the statement in the report of the cattle diseases committee that the available evidence as to the importance of milk in the spread of infectious disease was not conclusive, and that the number of cases of scarlet fever traced to milk in the last 20 years was only 2500 to 3000 out of some 2,000,000 cases.—Sir HILTON YOUNG replied: No, Sir. Even if it were established that only 2500 to 3000 cases of scarlet fever in the last 20 years were attributable to milk, I should still consider it important that milk should be pasteurised in order to prevent such cases in the future. But, in fact, the Committee on Cattle Diseases considered that infection through milk may be more extensive than appears at first sight, the reason being that it is only where a large number of cases occur that the milk-supply is likely to be suspected. Also, as my hon. friend is aware, scarlet fever is not the only milk-borne disease which can be prevented by pasteurisation.

Sir ARNOLD WILSON asked the Minister of Health whether he would draw the attention of medical officers of health to the statement, at page 28 of the report of the cattle diseases committee, that the most serious outbreak of disease brought to their notice, involving over 500 deaths, was traced to pasteurised milk infected by a human carrier.—Sir HILTON YOUNG replied : The outbreak in question occurred in Canada, and I understand that while it was not found possible to determine exactly how the milk became infected, the weight of evidence was to the effect that the infection was introduced before the milk reached the pasteurising depôt, and that much of the milk was distributed without having been submitted to the pasteurising process. I see no reason to call the special attention of medical officers of health to the matter.

Bookings at Maternity Hospitals

Mr. PARKINSON asked the Minister of Health whether, arising out of the Manchester case of Mollie Taylor, in which it was found that the porter of the hospital took all bookings for maternity cases and that these bookings bore no relation to the number of beds available, he would inquire in how many cases this practice of employing a porter obtained, and require that some qualified person, such as a lady almoner, should book the cases in relation to the number of beds available.—Sir HILTON YOUNG replied : Many maternity hospitals are outside my jurisdiction ; but I am advised that the method of booking referred to in the first part of the question is quite unusual. My medical officers inquire into the matter at the hospitals which they visit. As the hon. Member is no doubt aware, the published report on Mrs. Taylor's case contained a recommendation that the system of booking at the hospital concerned should be placed under the charge of a responsible officer.

Scarlet Fever at Denham and Iver

Sir FRANCIS FREMANTLE asked the Minister of Health whether he could make a further statement regarding the recent outbreaks of scarlet fever at Denham and Iver, Bucks, the number of cases and deaths involved, the origin of infection, and the administrative conclusions involved, with a view to the prevention of such outbreaks in future.—Sir HILTON YOUNG *replied* : Up to the present, 90 cases have been reported in which the signs and symptoms were sufficiently well defined to justify a diagnosis of scarlet fever, but there have been, in addition, a large number of mild cases in which the only clinical symptoms were sore-throat, vomiting, or slight fever. There have been two deaths. As regards the origin of the infection, I have nothing to add to the answer given on this subject on the 21st instant. The outbreak confirms the conclusion that it is practically impossible to avoid similar occurrences otherwise than by efficient pasteurisation, or some equally effective form of heat treatment, of the milk-supply.

Maternal Mortality

Captain ELLISTON asked the Minister of Health whether his attention had been drawn to the necessity of special local study of the causal factors of the continuing maternal mortality ; and what action he had taken or proposed to take in the matter.—Sir HILTON YOUNG replied : Yes, Sir. Such special study has been continuously in progress in the Ministry of Health. It was the main object of the special committee on maternal mortality appointed by one of my predecessors in 1928. I have myself recently carried the matter further as regards the local aspect by calling for special reports from the medical officers of health in the areas where the incidence is or has been most marked. I have further arranged for thorough local investigation of the problem in those areas and, for purposes of comparison, in other areas, by officers of the Ministry carefully selected for the purpose. I have secured the services of an eminent obstetrician to advise on the reports of those officers. Where immediate specific steps are recommended, I bring the matter to the notice of the authority for action accordingly. When all the reports are available I propose to consider the position as a whole and to lay a White Paper on the subject before the House.

Replying to Sir F. FREMANTLE, Sir HILTON YOUNG said he was afraid that he could not give a date when the White Paper might be expected, because it depended on the completion of intensive local investigations.

The Countess of IVEAGH : Has the right hon. gentleman taken into consideration the possibility of making compulsory a confidential notification of maternal deaths in all areas, as is now done in some areas ?

Sir HILTON YOUNG : Certainly that point has been under consideration, but at present the purpose is effectively served by the voluntary information which I get in response to my appeal to the local authorities.

Birmingham Infectious Diseases Hospital

Mr. GROVES asked the Minister of Health whether classified records had been kept regarding illnesses in nurses at the Birmingham City Infectious Diseases Hospital ; and, if so, for how many years were they available.—Sir HILTON YOUNG replied : According to information which I have received from the local authority, classified records of the illnesses of nurses in the Birmingham City Infectious Diseases Hospital are available for the years 1932 and 1933, and are set out in the Medical Officer of Health's Annual Reports for those years. Classified records for 1934 are not yet available.

MONDAY, APRIL 2ND

Royal Veterinary College

Sir ALAN MCLEAN asked the Minister of Agriculture whether the recommendations contained in paras. 44 and 45 of the Report of the departmental committee on the reconstruction of the Royal Veterinary College had been given effect to ; and if so, to what extent.—Mr. ELLIOT replied : The Governors have accepted in principle the recommendations to which my hon. and gallant friend refers, but action has been deferred until the rebuilding of the college is approaching completion. I understand that they have recently been advised that it will be necessary for them to apply for a new Charter, and that a draft is in course of preparation.

Private Maternity and Nursing-homes

Mr. EDWARD WILLIAMS asked the Minister of Health the number of private maternity and nursing-homes in the country, and the number that were registered and came under local government supervision.—Mr. SHAKESPEARE, Parliamentary Secretary to the Ministry of Health, replied : The administration of the Nursing Homes Registration Act, 1927, is in the hands of the local supervising authorities established under the Act, usually the councils of counties and county boroughs, and the information desired by the hon. Member is not in the possession of my right hon. friend. He would, however, point out that under the Act all private maternity and nursing-homes, with certain specified exceptions, have to be registered by, and are subject to inspection by, the local authority.

Local Authorities' Maternity Hospitals

Mr. EDWARD WILLIAMS asked the Minister of Health the number of deaths to mothers and children, respectively, at maternity hospitals which were administered by local authorities.—Mr. SHAKESPEARE replied : According to the returns received from local authorities in England and Wales for 1933, the numbers of deaths during that year of mothers and children in their maternity hospitals and in the maternity wards of other hospitals and institutions administered by them were as follows : 607 maternal deaths and 2243 deaths of infants within 10 days of birth. Complete figures for 1934 are not yet available.

Nutritional Value of Milk

Mr. COVE asked the Minister of Health whether he was now in a position to give the House any information as to the proposed inquiry into the nutritional value of milk at certain schools and approved centres.—Mr. ELLIOT, Minister of Agriculture, replied : Yes, Sir. The Milk Marketing Board for England and Wales, and the Scottish Milk Marketing Board, have submitted to the Secretary of State for Scotland and myself particulars of certain arrangements for conducting an inquiry into the nutritional value of milk. These arrangements have now been approved for the purpose of Exchequer contributions under Section 11 of the Milk Act, 1934, and in accordance with the provisions of that section have been laid before Parliament and are now available to the House. The cheme is supplementary to the milk in schools scheme, nd it is hoped that the information which will be collected rill not only be of great value to those engaged upon utritional research, and in connection with public health nd education services, but will also have an important earing upon the problem of increasing the demands for iquid milk in this country. As will be seen from the articulars in the White Paper, the inquiry is under the upervision of a representative expert subcommittee of he advisory committee on Milk Publicity of the Milk larketing Board for England and Wales, and is being onducted by experienced medical officers working in onjunction with school medical officers and teachers. It s on a large scale, covering some 8000 children, and is xpected to last for some twelve months.

Sale of "Prepared Honey"

Sir JOSEPH LAMB asked the Minister of Health if his ttention had been drawn to the sale of large quantities of a substance described as prepared honey, which was not the pure product of the bee from the nectaries of flowers; and what steps he proposed to take to prevent this misrepresentation of the nature of food as offered and sold to the public.—Sir HILTON YOUNG replied: I am aware that a substance which is not pure honey is being sold under the name of "prepared honey." I have no power to take any action in the matter, but if the circumstance of the sale are such as to constitute an offence under the Food and Drugs (Adulteration) Act, the duty of enforcement rests on the local authorities, and it is open to any person to take proceedings.

Discharge of Mental Patients

Dr. O'DONOVAN asked the Minister of Health if representations had reached his department or the board of control that the requirements of Section 49 of the Lunacy Act, 1890, had been altered within the last 10 years to the detriment of the friends or relatives who desired to secure the discharge of a patient; that previous to that date the two doctors appointed to examine a patient paid one visit each and reported, but now they were required to go together on two visits, thus doubling the cost in fees; and in view of the fact that such an increased cost was prohibitive to the poor he would look into this and see if it was possible to return to the practice previously obtaining.—Sir HILTON YOUNG replied: The requirements of Section 49 of the Lunacy Act, 1890, have not been altered, but some years ago the Board of Control, after careful consideration, expressed the opinion that the section requires that the two medical practitioners should examine the patient together on two separate occasions. Since 1928 the Board have received two representations in the matter. The point has been noted for consideration in the event of amending legislation being introduced.

PANEL AND CONTRACT PRACTICE

Married Women in Industry

IN the *National Insurance Gazette* of March 21st "Secretary" points out that the problem of married women in insurance has not been solved by the recent reduction in their sickness and disablement benefit. Circular 329 IC., which started the controversy, made it clear that married women's claims were more than double actuarial expectation. Lax certification by doctors was partly blamed for this, and eventually the rates of benefit were reduced by an amending Act of Parliament. Now, apparently, claims by men under the Act are less than was expected, whilst claims by women are equal to or more than expectation. The percentage of women claimants (being spinsters and widows) is only slightly higher than that of men, whereas the percentage of married women claimants is three or four times that of men and other women. The expectation of sickness is recognised to be higher for married women than for other insured persons, but it is thought still to be too high. Married women become insured in two ways: (1) as new entrants; (2) continuing insurable employment after marriage. As it has been suggested that many of both classes work only a few hours a week, and that insurance is therefore more profitable than employment, a study was made of 262 applications as new entrants when it was found that:—

6 per cent.	were employed about	1 hour	per day or less.
8 ,, ,,		2 hours	
12 ,, ,,		3 ,,	
20 ,, ,,		4 ,,	
29 ,, ,,		5 ,,	

These figures (which do not relate to Class 2) show that one in every three or four employed married women is engaged in what is virtually a spare-time employment, the remuneration for which may be little more and is sometimes less than sickness benefit. "Secretary" says that it is to a certain extent competent for societies to refuse admission to married women who are employed for less than a minimum number of hours. Many societies do not admit married women at all. This protects the society as far as new entrants are concerned, but not with regard to these continuing insurance after marriage. "Secretary" would like to find some method of weeding out those who are really whole-time housewives with some subsidiary work in insurable occupations; in the certification of such cases the doctor should, he thinks, take into consideration the hours of work at their employment. "Secretary" does not mention, as he might have done, that healthy married women who go out charing often evade insurance altogether. If their employers connive at this infringement of regulations and are not found out, the contribution for these healthy women are not forthcoming to help to pay benefit for the less robust chars, who immediately insist on being insured because they so frequently need it. This goes to swell the percentage of married women's claims.

Drugs and Appliances

Section 10 (2) of the National Health Insurance Act, 1924, provides that "medical treatment and attendance" includes the provision of proper and sufficient medicines, including such chemical reagents as may be prescribed, and of the prescribed medical and surgical appliances. Probably no aspect of the Act has caused more misunderstanding than the question what may or may not be prescribed as part of medical benefit. It is sometimes suggested that insurance practitioners are not permitted freely to order medicines which are not included in the National Formulary, but reference to the introduction to the volume itself will reassure the doubter that the Formulary in no way affects the right of a medical practitioner to order such proper and sufficient medicines for his patients as the terms of his agreement with the insurance committee require. Any practitioner may write extemporaneous prescriptions independently of the Formulary or of the Drug Tariff, although he should bear in mind that the chemists' fund is limited, and therefore combine efficiency and economy. Insurance practitioners are advised not to order proprietary preparations unless they have satisfied themselves that the therapeutic effect aimed at cannot be obtained by the use of non-proprietary remedies. A list of what are regarded as efficient substitutes for a number of proprietary preparations is incorporated in the National Formulary, and a practitioner who has prescribed a proprietary preparation for which a recognised substitute of lower cost is available, and who has failed to give such substitute a trial, may find difficulty, when challenged, in justifying his action.

The London insurance committee, on March 28th, considered a report by their medical benefit subcommittee giving instances of expensive drugs and appliances recently prescribed—quite properly—for insured persons. Scrutiny of the prescriptions received from chemists had satisfied the subcommittee that practitioners are not unmindful of their duty to prescribe proper and sufficient medicines for insured persons. Inquiries have often to be addressed to manufacturers asking for prices and particulars of new remedies prescribed for insured persons, the introduction of which is so recent that they have not yet been included in the makers' latest lists.

Fees Charged to Insured Persons

During a period of two months thirteen applications were made to the medical benefit subcommittee in a large urban area for the withdrawal of accounts rendered by practitioners or the refund of fees, paid in respect of medical treatment provided for insured persons. Action was taken as follows:—

In one case the account was cancelled as the insured person's name was included in the practitioner's list, and the account had been rendered in error.

In two cases the amounts were refunded as the insured persons were entitled to receive treatment as insured persons.

In three cases no action was taken, as the insured persons' names appeared in the lists of neighbouring practitioners, and the necessary transfers had not taken place.

In three cases no action was taken as application was not made within the specified time—viz., one month from the date of the presentation by the practitioners of the accounts, and in two of the cases treatment was provided in a private capacity.

In one case the account was withdrawn, the practitioner providing treatment as deputy for a neighbouring practitioner.

In the remaining three cases no action was taken as treatment was provided in a private capacity.

PUBLIC HEALTH

Flat-foot in School-children

NOT long ago Mr. Blundell Bankart pointed out to the Medical Society of London that a flat-foot is not in itself a deformity, nor a malady, nor indeed any disability whatever; it is the natural attitude of the foot in relaxation. The arched condition of the sole of the foot is an attitude or posture determined by muscular action, and maintained only so long as the muscles are in action. The so-called arch of the foot—which anatomists for centuries have taught is the normal condition, and which orthopædic surgeons have been at such pains to preserve—is a contracture deformity almost universally acquired as the result of cramping the foot in a shoe. If this is so, the wearing of sandals and plimsolls should preserve the natural mobility of the child's foot by permitting it to flatten when the weight of the body is on it.

Officers of the school medical service should have the best chance of verifying this. Recently a number of assistant medical officers in Kent were asked to report on the relation of flat-foot to the wearing of what are now called plimsolls. Do these heelless rubber shoes cause any pathological condition of flat-foot? Dr. C. Campbell agrees with Mr. Bankart that the arch of the foot is maintained not by ligaments but by muscles; a pathological condition exists only when the muscles become so fatigued that postural reflex activity is exhausted. He divides the flat-foot of school life into two types—(1) supple, where loss of function is negligible; (2) rigid, with considerable loss of function; but he does not give the proportion of his types. In a school where plimsolls are worn he found flat-foot (undefined) to be slightly commoner than in other schools where they are not worn, but he regards them as harmless to normal feet if the children are not required to stand in them for long periods at a time. Where however there is any predisposition, e.g., weak ankles, poor muscular tone, bad posture in standing and walking, wearing plimsolls will accelerate the development of flat-foot. Dr. W. Lessey and Dr. J. Selfe can find no evidence that the wearing of plimsolls is a cause of flat-foot, but Dr. Gladys Stableforth gives tables which suggest that the proportion of flat-footed children is much higher in schools where plimsolls or sandals are worn; it was 25 per cent. in one school where plimsolls were worn all day. Obviously the wearing of plimsolls makes it easier to spot the feet which lose their arch when the weight of the body is on them, but Dr. Stableforth had other criteria than this. But neither in her figures nor in Dr. Campbell's is there any exact evidence that they were dealing with a pathological condition. On the other hand, most boots and shoes restrict the movement of the feet, and the resulting loss of suppleness must tend to the acquirement of the real disability of foot strain.

But however unconvincing may be the evidence of disability due to the wearing of such simple footgear, flat-foot is not uncommon in schools, and the suggestions for treatment made in this combined report have their value. Dr. Campbell remarks that many cases occur during adolescence, the majority of which could have been prevented by measures taken at school to correct faulty habits and develop weak muscles. Dr. Stableforth blames a faulty stance. Few children, she says, know the correct way of walking or standing; many of them turn the toes out and allow the weight to fall on the inner border of the foot, putting an enormous strain on the arch. Walking, as distinct from marching, is not, it seems, included in the curriculum for gymnastic instruction. But it is encouraging to see that the foot is receiving increased attention from physical training instructors in coöperation with the medical officers and at the remedial exercise clinics under the guidance of orthopædic surgeons.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 23RD, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2708; diphtheria, 1517; enteric fever, 22; acute pneumonia (primary or influenzal), 1690; puerperal fever, 56; puerperal pyrexia, 157; cerebro-spinal fever, 22; acute poliomyelitis, 3; encephalitis lethargica, 4; dysentery, 13; ophthalmia neonatorum, 94. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on March 30th was 3863, which included: Scarlet fever, 1120; diphtheria, 1717; measles, 11; whooping-cough, 312; puerperal fever, 26 mothers (plus 10 babies); encephalitis lethargica, 269; poliomyelitis, 1. At St. Margaret's Hospital there were 22 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 20 (1) from measles, 4 (1) from scarlet fever,

CORRESPONDENCE

MYASTHENIA GRAVIS

To the Editor of THE LANCET

SIR,—I have been engaged during the past month in investigating the feasibility of the oral administration of Prostigmin for the treatment of myasthenia gravis over long periods. I was therefore much interested to read Dr. Denny-Brown's letter in your last issue. The result which he obtained in his patient by giving orally tinct. belladonnæ ♏ xx. followed by physostigmine salicylate gr. 1/6 was most encouraging. The action was comparable in degree and duration to that of a hypodermic injection of prostigmin (2 mg.). No unpleasant effects were noticed apart from some weakness of the pulse and general faintness during the first two hours.

I have had an opportunity of testing this method on three cases of myasthenia whose reactions to prostigmin by injection have been repeatedly investigated by myself and found to be very nearly constant. The result which I obtained with the oral administration of physostigmine has been so different from the one described by Dr. Denny-Brown that it is obvious that individual patients may show marked tolerance or, on the other hand, great susceptibility when this drug is exhibited. I feel that my results might be helpful to any of your readers who are at present engaged in the treatment of cases of myasthenia.

CASE 1.—Tinct. belladonnæ ♏ xv. in water, followed fiteen minutes later by physostigmine salicylate gr. 1/10. Half an hour later the patient showed some improvement and about the same time complained of eructations and epigastric discomfort. The improvement lasted about an hour. The same patient, after an injection of prostigmin 0·5 mg., experiences a greater improvement lasting two and a half hours. No discomfort is felt although no atropine is given.

CASE 2.—This case also responds favourably to prostigmin 0·5 mg., without atropine. Very limited ocular movements are restored to a full range. The grasp increases from 2 lb. to 14 or 15 lb. She received tinct. belladonnæ ♏ xx. followed in fifteen minutes by physostigmine salicyate gr. 1/8. No improvement occurred. On the other hand she complained of epigastric pain, a feeling of coldness, and she vomited an hour and a half after taking the drug.

CASE 3.—After an injection of prostigmin 0·5 mg., this case shows a diminution of ptosis, and an improvement in the grasp from 5 lb. to 18–20 lb. The effect lasts about two hours. She was given tinct. belladonnæ ♏ xx., followed in fifteen minutes by physostigmine salicylate gr. 1/8. No subjective or objective improvement was noticed. She was cold and shivery for about two hours, she complained of epigastric pain and nausea, and at one time members of the nursing staff were alarmed at her condition as her pulse was barely palpable.

In view of my experience I feel that caution is necessary when using physostigmine, especially as the cases recorded here received smaller doses than the ones used by Dr. Denny-Brown, and showed signs of intolerance to such an extent that the desired improvement was not obtainable.

I am, Sir, yours faithfully,
L. P. E. LAURENT.
University College Hospital, W.C., April 1st.

To the Editor of THE LANCET

SIR,—It does not detract from the importance of Dr. M. Walker's discovery of Prostigmin in the treatment of myasthenia gravis to recall that American observers have for some years reported equally good results by amino-acid therapy. To take one example from the numerous reports in the American literature, Boothby (Jour. Amer. Med. Assoc., 1934, xxi., 1599) says :—

> "In a series of 46 cases of myasthenia gravis treated with glycine and usually also with ephedrine, all but two responded favourably ; 13 patients are walking, 8 greatly benefited and doing light work, 15 are moderately improved, and 3 have just started treatment."

On theoretical grounds there might be some justification for combining prostigmin and glycine therapy, since the glycine might, by providing the creatine necessary for muscular contraction, avoid the danger of "flogging a tired horse" to which Dr. Denny-Brown refers in his letter in your last issue.

I am, Sir, yours faithfully,
DOUGLAS HUBBLE.
Derby, April 1st.

PROGNOSIS IN PULMONARY TUBERCULOSIS

To the Editor of THE LANCET

SIR,—In Dr. Vere Pearson's article on Prognosis in Pulmonary Tuberculosis (March 23rd) I was pleased to observe the following passage: "The calling of which the patient has experience is generally the easiest and most lucrative and should not be lightly abandoned." It is surprising how frequently one encounters tuberculous patients who have been advised to give up a quiet sedentary occupation with a living wage in exchange for "an open-air job" (no practical details suggested). Too often the town-dweller visualises country life as an idyllic existence "midst sun-kissed cornfields and pleasant orchards." A slushy farmyard at 5 A.M. in February is a different picture—but must needs be faced. Farming to-day often offers but a lean livelihood to the experienced man born and bred in the country; what are the prospects for a weakly tuberculous ex-clerk with a wife and family to support ?

I am, Sir, yours faithfully,
T. WARWICK PRESTON.
Queen Anne-street, W., March 27th.

THE PSYCHONEUROSES

To the Editor of THE LANCET

SIR,—I must agree with your leading article that the study demanded for the diploma of psychological medicine, and even for the doctorate in psychological medicine, is of little value in the actual conduct of analytical therapy. The knowledge demanded for the diploma is related to psychotherapy in much the same way as anatomy is related to surgery, and to

---

(*Continued from previous page*)

30 (5) from whooping-cough, 61 (6) from diphtheria, 49 (8) from diarrhœa and enteritis under two years, and 175 (24) from influenza. The figures in parentheses are those for London itself.

There has been a further substantial rise in the number of deaths attributed to influenza, the deaths for the last few weeks (working backwards) being 175, 145, 139, 83, 91, 83, 91, 71, 56. This week these deaths were distributed over 65 great towns, Liverpool reporting 19, Stoke-on-Trent 14, Manchester 11, Warrington, Birmingham, Cheltenham, and Cardiff each 4, West Ham, Willesden, Darlington, Rochdale, St. Helens, Sunderland, Derby, and Swansea each 3. Five fatal cases of diphtheria were reported from Birmingham, 4 from Portsmouth, 3 each from Liverpool, Manchester, Sunderland, and Merthyr Tydfil. Hull reported 5 deaths from measles, Wigan 2. The 2 deaths from enteric fever occurred at Hull and Liverpool.

The number of stillbirths notified during the week was 309 (corresponding to a rate of 45 per 1000 total births), including 41 in London.

hold the diploma is no more proof that the diplomate is capable of performing analytical therapy than the possession of skill in anatomy is an indication of capability of performing a surgical operation. The only way in which one can acquire psychotherapeutic skill is either by wide clinical experience working under the guidance of one who has mastered this work or by undergoing a personal analysis.

Your attitude regarding the knowledge of organic neurology appears to me to be indefensible. Surely a sound knowledge of organic neurology is essential unless the psychotherapist is to be a mere ancillary to the neurologist. It opens the whole question of lay analysis which is not desirable as a general rule. It is, however, just as important that the neurologist should have sufficient knowledge of the psychoneuroses. A short time ago I was surprised to hear an eminent neurologist label an obvious anxiety neurotic as a "congenital psychasthenic" for whom nothing could be done except the provision of the traditional bottle of bromide.

It seems a pity that it is not possible to provide an additional diploma to the two already bestowed by London University. The present two varieties are for special knowledge in psychiatry and for special knowledge in mental deficiency. The third type would be for special knowledge in psychotherapy, and those wishing to acquire this diploma would have to give evidence of really having performed analyses and undergone *training in analytical technique.*

It appears to me that Dr. Henry Wilson is correct in deploring the fact that medical superintendents of mental hospitals have been given control of clinics for psychotherapy. The work of the mental hospital medical officer is mainly administrative and most mental hospital medical officers know little of the technique of psychotherapeutic work. His suggestion of the establishment of part-time posts is in my opinion an excellent one.

I am, Sir, yours faithfully,

March 30th. CLIFFORD ALLEN.

DETECTION OF LEAD POISONING

To the Editor of THE LANCET

SIR,—I have read with interest your leading article on the Detection of Lead Poisoning in THE LANCET of March 2nd. "A Thirty-Minute Spectrographic Micro-Method for the Detection of Pathological Lead in Peripheral Blood," on which you comment, was developed by Scott and myself for its practical value in expediting the diagnosis of lead poisoning rather than for purely scientific value. There are certain statements in your comment which convince me that we failed to make ourselves clear in our article. You say, "The authors claim that a positive result 'indicates lead poisoning, or an early stage of convalescence from it'; but consideration of the results obtained by R. A. Kehoe et al. throws some doubt on the justification for this conclusion." With reference to the level of lead in the blood of a group of medical students, which corresponded to 0·06 mg. per 100 c.cm. of blood, it is further stated, "This amount is equivalent to 0·06 γ in 0·1 c.cm., and it is noteworthy that its presence would give a positive result in the test for lead encephalopathy devised by Blumberg and Scott."

A "positive result," in the sense in which we used the term, is not the detection of lead, but the detection of pathological lead, and is defined as the result in which "the sensitive lead line at 2833·07 Angstrom units would appear visible to the eye, and the minor lines at 2802·09 A.U. and 2614·20 A.U. could be seen with the aid of a lens." Thus, 0·05 mg. per 100 c.cm. could be detected, but the truly pathological range does not begin until the concentration reaches 0·2 mg. per 100 c.cm. This means, of course, that 0·06 mg. per 100 c.cm. could be *detected*, but would be a non-pathological trace and considered a negative rather than a positive result. Dr. Scott and I have reported, of course, on the occurrence of non-pathological traces of lead in normal blood, and well recognise that the detection of such a trace does not indicate lead poisoning. Our findings in regard to the level of lead in the blood and the appearance of lead poisoning were reported on May 1st, 1934, and have appeared in a preliminary note (Amer. Jour. Dis. Child., 1934, xlviii., 1437). We have *just submitted a detailed* report for publication, in which the following values have been established from our data:—

Non-pathological	0·005–0·1 mg.	per 100 c.cm.
Pathological borderline.. ..	0·1 –0·2 ,,	
Pathological (lead poisoning or convalescence)	0·2 –1·0 ,,	

Our results show that there is no more lead in the blood of normal adults than of the children studied. So far as our own results are concerned, the values in children tend to exceed slightly those in adults, presumably due to pica or a previous epidemic of storage battery lead poisoning in Baltimore, but many of the patients seen in Dr. Park's clinic at the *Harriet Lane Home are of the poor negro class* and may not give representative results.

I am, Sir, yours faithfully,

HAROLD BLUMBERG,

Department of Biochemistry, The Johns Hopkins University, Baltimore.

March 18th.

THE ROYAL VICTORIAN ORDER.—The following promotions and appointments have been made in the Royal Victorian Order, on the occasion of the visit of the Duke of Gloucester to Australia and New Zealand. To be Members of the Fourth Class: Surgeon Commander Alexander William Gunn, M.B., R.N.; Surgeon Lieut.-Commander Lionel Lockwood, M.D., R.A.N.

SEAMEN'S HOSPITAL SOCIETY.—The annual court of governors of this society was held on March 28th at the Mayfair Hotel, with Lord Howe in the chair.

The annual report was presented by Sir Ion Hamilton Benn, who said that the income from patients' payments had gone up, while subscriptions from the public remained about the same and the income from legacies had gone down. The balance sheet showed on the year's working a deficit of £633. There was an increase in expenditure. Some of the branches, had, however, made a good showing, notably Tilbury Hospital, which during the year had reduced the deficit on its working by £1000, and the Hospital for Tropical Diseases, which had been able, mainly through increased receipts on account of services to patients, to convert a deficit of £1500 into a credit balance of some £300. The board of management had made a change for their nursing staff from an affiliated training school to a self-contained training school, which meant that the nurses would receive a more compact training in a shorter time. They were also still hopeful that it might be possible to enlist the assistance of the shipping companies to make the post-graduate courses for ship surgeons an integral part of the curriculum of the Mercantile Marine. In proposing the adoption of the report, Lord Howe made an appeal for £40,000 to build a new hospital with a nurses' home, at the Albert Dock. The Port of London Authority had presented the society with a site and the sum of £25,000. Capt. Euan Wallace seconded the proposal and the report was adopted by the meeting. Vice-Admiral R. M. Colvin and Sir Charles McLeod were elected to the board of management.

OBITUARY

SIR EDWARD SHARPEY-SCHAFER, F.R.C.P. Edin., F.R.S.

EMERITUS PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF EDINBURGH

WITH the death of Sir Edward Sharpey-Schafer, which occurred at his house in North Berwick on Friday, March 29th, a great figure is lost to scientific medicine. He earned prominence by work in histology performed more than half a century ago, and from that time throughout his long career he remained in the van of physiological research, making fundamental additions to scientific knowledge.

[Photograph by Elliott and Fry

SIR E. SHARPEY-SCHAFER

Edward Albert Schafer (known to all the present generation as Sharpey-Schafer) was born in London in 1850, the son of Mr. J. W. Schafer, of Highgate, who had also German connexions. He was educated at Clewer, Windsor, before entering University College, London, where he joined the medical school attached to University College Hospital. He was a pupil of William Sharpey during the last years of that great man's occupancy of the chair of physiology and anatomy at the College. When a studentship at the College was founded in Sharpey's honour, Schafer became in 1872 the first Sharpey scholar, while he was already marked out as showing exceptional promise by the awards of scholarships at London University in zoology, anatomy, and physiology. In 1874, having qualified as M.R.C.S., he became assistant professor of physiology at the College, where Burdon-Sanderson succeeding Sharpey occupied the new Jodrell chair—the first separate chair in physiology to be established in England. Michael Foster was the chief demonstrator. Schafer's earlier work was almost entirely histological, and his publications on the structure of striped muscle-fibres became classical. His first paper dealt with the coagulation temperatures of the blood proteins and he followed this with classical studies on the histology of fat absorption. His position was soon established as a leader of his science; he was one of the founders of the Physiological Society in 1876, and was elected F.R.S. in 1878, an unusually young recipient of the distinction. In 1883 he was elected Jodrell professor, a post which he was to hold for the next 16 years. During this period his contributions to medical science were of the first importance. In 1885 he wrote his well-known text-book, "The Essentials of Histology," which has passed through 13 editions, the latest appearing only last year. The book was a practical expression of words in his introductory address to the students of the medical school in that year, when he regretted the general assumption of those in charge of medical education at the time that anatomy was the foundation on which the whole superstructure of medical and surgical science could be reared. He pointed out that the assumption could only be justified if "the object of medical education were to provide physicians not for the living but for the dead," and his text-book had for its object the supplying to students of the many data necessary for the comprehension of physiological processes. The book in its various editions has endured much revision and has been of the highest practical value to many generations of students. Schafer had already proved the logical necessity of the microscopic study in association with systematic anatomy in the eighth edition of Jones Quain's Anatomy, of which he was a co-editor, and in which the histology of the various structures and organs was displayed.

Schafer now took up work on cortical localisation and on the rhythm of muscular response, publishing his results in 1887 and 1889, while in 1891 appeared researches on ciliary and amœboid structure, followed by those on the structure of the fovea. In work on the heart he was among the first, if not the first, to use methods of photographic record. His invention of the plethysmograph was followed by well-known studies on the contractions of the spleen. In collaboration with George Oliver, he published researches showing the effects produced by the intravenous injection of extracts made from the chromaphil tissue contained in the medulla of the adrenal body, these being pioneer investigations into the activities of the animal extracts. The authors showed that extracts of the suprarenals and the pituitary contained substances which raised the blood pressure, and they must be regarded as the initiators of much of the endocrinology that has followed.

In 1898 he undertook the editorship of the text-book of physiology by British authors, an undertaking which achieved a success quite unusual where the work of many authorities is recorded in collaboration; it became immediately a standard book of reference on physiology throughout the world. This was not surprising considering the band of contributors he was able to secure, among whom were Gowland Hopkins, E. H. Starling, Benjamin Moore, and W. D. Halliburton. Schafer wrote on metabolism and the internal secretions, and supplied an inclusive summary of the enormous subjects. Each of the articles was a complete monograph written out of particular knowledge. To physiologist, pathologist, and physician alike in search of minute fact to support any given theory or opinion the book became an invaluable work of reference.

The second volume of this text-book appeared just after Schafer had accepted, in 1899, the chair of physiology at the University of Edinburgh, and here he returned to work on the tracts of the spinal cord which had held his particular attention some 10 years previously. Afterwards he investigated the intracellular blood canaliculi of liver cells, and published researches on pulmonary blood pressure, on the effects of vagotomy, and on the return of sensory functions in the skin after denervation. Some of his results were verified by experimentation on his own person, the last of them being performed only 10 years ago when he was already an old man. While at Edinburgh, also, he devised his method for the performance of artificial respiration on the apparently drowned, a piece of practical work for the performance of which he is widely known to the public, and which gained for him the distinguished service medal of the Royal Life Saving Society.

In 1913, the year when he was knighted, Schafer delivered the Lane lectures at Stanford University, California. These were published first in abbreviated form without illustration, but a revised issue which followed, was greatly enhanced in value by the profuse addition of tracings and photographs. The lectures, when published under the title of "The Endocrine Organs," formed a luminous and concise account of the state of knowledge at that date concerning the highly important glands, and the book was re-published in two volumes in 1924 and 1926. It is unnecessary to point out the authoritative nature of a work which is so constantly quoted, and apart from the voluminous and concise nature of its information the critical faculty exercised by the author—his method of dealing with controversial questions—is particularly to be commended. He founded also the *Quarterly Journal of Experimental Physiology* and continued to edit it until his retirement from the chair at Edinburgh, in 1933, when the editorship passed to Prof. I. de B. Daly. On his retirement his assistants published a special volume of this journal in his honour, which the recipient edited himself, while its contents were entirely composed of original researches by the collaborators.

The appointments held by Sir Edward Sharpey-Schafer (the addition to his surname was made in 1918) were numerous and important, and his name must have been known to the public more widely than that of any other physiologist. He was general secretary to the British Association for the Advancement of Science for 5 years from 1895–1900, and president of that body in 1912. For 47 years a fellow of the Royal Society, he received a Royal medal in 1902 and the Copley medal in 1924. He was a medallist of the Royal Society of Edinburgh and was awarded the de Cyon prize of the Academy of Sciences of Bologna. In 1923 he was president of the International Physiological Congress. He was an honorary fellow, associate, or corresponding member of numerous continental and American bodies. The Royal College of Physicians of London gave him the Baly medal, and the sister college of Edinburgh made him an honorary fellow. He received doctorates in medicine, science, or laws from exactly a dozen universities, British, continental, and American, and all who knew the strenuous and valuable nature of the researches thus recognised found that the honours were the due reward of merit. He lived for physiology, and the abiding inspiration of his career was summed up by himself when addressing in Edinburgh an Inter-State Post-Graduate Assembly of North America a few years ago. Speaking of the relationship of physiology to medicine he said that no line of demarcation could be drawn between any of the branches of science associated with medicine. "In one direction physiology borders on pathology, in another on pharmacology, in another on chemistry, in another on physics, in another on general biology both of animals and plants." No one has ever more clearly shown that a branch of science, whatever it may be, cannot be dealt with unless its relationship to other branches is taken into account. To prove the application of this axiom to the relationship between physiology and medicine was his life's work.

Sir Edward Sharpey-Schafer was married twice, first in 1878 to Maude, daughter of Mr. A. W. Dixie, and secondly in 1900 to Ethel, daughter of Mr. J. H. Roberts, F.R.C.S. His widow and a daughter survive, but he endured the tragedy of losing both his sons in the war.

We have received the following tribute from Dr. W. A. Bain, lecturer in physiology at the School of Medicine, Leeds: "As the last of Schafer's pupils to devote himself to full-time teaching and research in physiology, and the last also to have actually worked with him, may I be permitted to pay tribute, however inadequately, to his memory? To most Sharpey-Schafer is known only by his writings; to some thousands he was known as a teacher; to some hundreds as a fellow physiologist; and to a few as a chief and a friend. Of all who came into more or less personal contact with him, the most highly privileged were those who had the honour of working with him or under him, for they could fully appreciate the true greatness of the man.

"Schafer was fortunate in the influences which played on and superimposed themselves on his own brilliant natural gifts, and in him could be plainly discerned the chief characteristics of three of the greatest figures in 19th century physiology; Sharpey, the histologist; Ludwig, the experimentalist, whose very appearance Schafer seemed to acquire; and Michael Foster, the teacher. His first paper was on a histological subject and, as he delighted to recall, was rejected by the Royal Society only to be hurriedly published some time later after a similar paper by the Hertwigs had appeared in a Continental journal and been loudly acclaimed. Schafer's interest in histology was always maintained. He held very strongly to the view that histology should be an integral part of the physiological curriculum, and he never tired of deploring the modern tendency to separate the two subjects and relegate the teaching of histology to the anatomists and the anatomical laboratory. As an experimentalist, even in his latter years, he combined a splendid technical ability with a flair for getting at the essentials of a problem and an almost uncanny genius for assessing the significance of a result. This last faculty was a remarkable thing—incomprehensible in its operation, but generally justified in its results. It sometimes led him to make prophetic utterances, the wisdom of which was demonstrated years later in the natural march of science.

"Schafer's classroom was one of the greatest tributes to the power of his personality. Edinburgh classrooms were never noted for the good order observed in them, and few things could be more dramatic than the sudden transition from the babble of 200 voices to a stillness as of the grave when Schafer appeared at the door of his theatre and made his way slowly, and with characteristic step, to the rostrum. Many a time the one o'clock gun went off as Schafer was talking. In probably any other lecture theatre in the university that would have been the signal for pandemonium, but Schafer was permitted to go on. The admiration of the student for Schafer was mixed with fear, but to those who knew him he was, under the somewhat stern exterior, the kindliest and friendliest of men, with a keen sense of humour and a very charming smile. His memory was marvellous, and many a time his colleagues and pupils have been enthralled as he recounted incidents and anecdotes of many years ago as though they were of yesterday—and there was an incident or an anecdote a propos of almost anything, such was the length and breadth of his experience. And what a joy it was to hear him talk. He had a mastery of the English language, and the beauty and precision of his diction must have been a revelation to everyone who heard him. Though we shall see and hear him no more, his influence and example will live on, and will continue to be for many of us the principal inspiration of our lives."

THOMAS JEFFERSON FAULDER, M.B., B.Chir. Camb., F.R.C.S. Eng.

THE death occurred on March 20th of Mr. Jefferson Faulder, senior surgeon to the Throat Hospital, Golden-square. He was a distinguished classical scholar as well as an accomplished laryngologist.

Thomas Jefferson Faulder was born at Carlisle in 1871 and received his education at St. Bees School, whence he proceeded to Clare College, Cambridge, in 1889 as senior classical scholar. He obtained a first class in the classical tripos in 1893, and deciding to follow medicine joined the medical school at St. Bartholomew's Hospital, obtaining the Jeaffreson exhibition in 1898, and scholarships with regularity for the next two years, culminating with the Brackenbury scholarship in 1903. In this year he obtained the English double diploma, and in 1904 proceeded to the F.R.C.S. Eng.; in 1905 he graduated as M.B., B.Chir. Cambridge. At St. Bartholomew's Hospital he was house surgeon to the late Harrison Cripps, and for three years acted as junior demonstrator of anatomy. In 1907 he became chief assistant in the throat department of the hospital, a post which he held for six years, during which time he made sound clinical contributions on various aspects of his specialty to *St. Bartholomew's Hospital Journal* and also to the *British Medical Journal*. While engaged in the laryngological work at St. Bartholomew's he was elected to the staff of the Golden-square Hospital and also was appointed surgeon to St. Marylebone General Dispensary, and when the war broke out he was leading a very full professional life. During the war he served with the 92nd Brigade, R.F.A., and received the Territorial Decoration; he later recorded in the *British Medical Journal* some interesting reflections on the relationship between military and occupational diseases. After the war he resumed his duties at his hospitals and practised successfully his specialty of laryngology.

Mr Jefferson Faulder married a daughter of his chief, Mr. Harrison Cripps.

SIR HORACE PINCHING, K.C.M.G., M.R.C.S.

LATE DIRECTOR-GENERAL, PUBLIC HEALTH DEPARTMENT, CAIRO

THE death occurred on March 28th of Sir Horace Pinching at Cairo, where he had for many years resided and where as a distinguished public servant he was well known.

Horace Henderson Pinching was the son of Mr. G. J. Pinching, J.P., of Gravesend, Essex, and was educated at Epsom College and Pembroke College, Oxford. He graduated in arts at Oxford and came for his medical training to St. George's Hospital, took the English double qualification in 1883, and entered immediately the R.A.M.C. He was seconded for service in the Egyptian army in 1888, and six years later was transferred to the public health department of Egypt. He found there much to do, for the public health of Egypt was deplorable, while all efforts at reform met with serious resistance. Cholera constantly made its appearance, and the population was gravely affected also by parasitic diseases and infectious ophthalmia. In carrying into effect measures of reform Pinching distinguished himself by the character of his work, and in 1899 he became Director-General of his department, a post which he held for nine years. He was decorated by the Khedive and was appointed K.C.M.G. shortly before his retirement.

Sir Horace Pinching married in 1903 Ednée, daughter of Mr. Ernest Cramer, of Pressy, Geneva, by whom he had two daughters. He spent the last years of his life in Switzerland.

MEDICAL NEWS

University of Oxford

Dr. R. C. MacKeith has been elected a fellow of University College on the foundation of Dr. John Radcliffe. The Radcliffe prize for the furtherance of medical science in the University has been awarded to Dr. C. L. Cope.

University of London

At recent examinations the following candidates were successful:—

D.M.R.

Part I.—F. M. Abeles, P. A. Flood, Daniel Hugo, E. G. Lynch, Mahendra Mani, Stanley Nowell, and Tek Chand Wasson.

University of Leeds

At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—G. N. Blackburn, Olive M. Callow, J. C. Coates, Joan M. Coward, W. Davidson, W. G. France, M. Headlam, W. Hobson, K. K. Hussain, R. L. Lamming, D. M. Leiberman, D. J. McCandlish, S. Mattison, W. S. A. Oakes, R. Petticrew, G. Quayle, S. H. Samuel, Winnie Shaw, C. E. Stuart, and C. W. Ward.

Part II.—Mary Barraclough, T. M. Boyle, Julia M. Brown, D. F. Cameron, G. A. Collinson, W. G. L. Flather, Irene Haslegrave, E. H. Kitching, E. F. Lai, H. T. Levi, A. E. Penn, F. Reid, H. Silman, H. E. Steward, and C. C. N. Vass.

Part III.—E. H. Kitching (First-class Honours), G. A. Collinson (Second-class Honours), Mary Barraclough, T. M. Boyle, Julia M. Brown, D. F. Cameron, W. G. L. Flather, Irene Haslegrave, E. F. Lai, H. T. Levi, A. E. Penn, L. Rabinovitch, F. Reid, H. R. Rollin, H. Silman, H. E. Steward, D. Thackray, and C. C. N. Vass.

L.D.S.

K. S. Armstrong-Lamb, T. Stirling, T. H. H. Wilson, and T. J. Wood.

British College of Obstetricians and Gynæcologists

The following candidates have been awarded the diploma of the College after examination:—

A. K. Acharya, Annie F. Allport, W. N. Brown, Helen R. Buck, Dora Davies, Muriel H. Deem, S. K. Hutton, C. N. Jeffries, Mary K. Lawlor, Barbara H. Mitchell, James Morrissey, E. B. Murrell, J. L. Parker, Helen I. Robertson, Isabella Taylor, and S. W. Wright.

University of Liverpool

Among those who will receive the honorary degree of LL.D. at the graduation ceremonies of the University on May 24th are Prof. Arthur Harden, F.R.S., formerly director of the biochemical department of the Lister Institute, and Mr. C. Thurstan Holland, F.R.C.S., formerly lecturer in radiology at the University and president of the first International Congress of Radiology.

University of Manchester

Applications are invited for a travelling research scholarship in medicine and for pathological scholarship. Candidates must be graduates of the university who have taken the full course of clinical instruction at the Manchester Royal Infirmary. Further details may be had from the secretary of the infirmary, to whom applications should be sent not later than May 4th.

Post-graduate Course at Freiburg

A medical post-graduate course is being held at Freiburg from July 1st to 23rd, at which members of the medical faculty will give lectures. Opportunity will be given for members of the course to take part in the work of the various clinics. The secretary of the course is Prof. C. Noeggerath, Kinderklinik der Universität, Freiburg i. B. Mathildenstr. 1.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.
Thursday, April 11th.—8 P.M., Mr. Stanford Cade: Radiation Treatment of Carcinoma of the Lungs.

HUNTERIAN SOCIETY.
Monday, April 8th.—8.30 P.M. (Simpson's Restaurant, Cheapside), Annual General Meeting. Lieut.-Col. R. H. Elliot: Snakes and their Bites.

LONDON JEWISH HOSPITAL SOCIETY, Stepney-green, E.
Thursday, April 11th.—3.30 P.M., clinical meeting.

SOUTH-WEST LONDON MEDICAL SOCIETY.
Wednesday, April 10th.—9 P.M. (Bolingbroke Hospital, Bolingbroke-grove, S.W.), Dr. G. E. S. Ward: The Failing Heart.

SOCIETY FOR THE STUDY OF INEBRIETY.
Tuesday, April 9th.—4 P.M. (11, Chandos-street, W.), Dr. E. W. Adams: What is Addiction?

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY.
Thursday, April 11th.—8.30 P.M., Dr. M. S. Thomson: The Psychological Aspect of Skin Disease.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
Monday, April 8th, to Saturday, April 13th.—Infants Hospital, Vincent-square, W. Afternoon course in infants' diseases.—Royal Eye Hospital, St. George's-circus, S.E. Afternoon course in ophthalmology.—St. Mark's Hospital, City-road, E.C. All-day course in proctology.—Courses are open only to members and associates of the Fellowship.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
Monday, April 8th.—Noon, Dr. D. Nabarro: Septicæmia. There will be out-patient clinics every day at 10 A.M. and ward visits (except on Wednesday) at 2 P.M.

CANCER HOSPITAL (FREE), Fulham-road, S.W.
Thursday, April 11th.—4 P.M., Prof. J. M. W. Morison: The Treatment of Cancer by Radiations.

PRINCESS BEATRICE HOSPITAL, Richmond-road, S.W.
Thursday, April 11th.—9 P.M., Mr. A. Lawrence Abel: The Acute Abdomen.

TUBERCULOSIS ASSOCIATION.
Thursday, April 11th, to Saturday.—Annual Meeting will take place in Oxford.

GENERAL INFIRMARY, Leeds.
Tuesday, April 9th.—3.30 P.M., Dr. Towers: Demonstration of cardiological cases.

LEEDS PUBLIC DISPENSARY AND HOSPITAL.
Wednesday, April 10th.—4 P.M., Mr. L. N. Pyrah: Hæmaturia and its Significance.

ROYAL INFIRMARY, Manchester.
Tuesday, April 9th.—4.15 P.M., Mr. John Morley: Clinical Aspects of Diverticulitis of the Intestinal Tract.
Friday.—4.15 P.M., Mr. G. Jefferson: Demonstration of neurosurgical cases.

ANCOATS HOSPITAL, Manchester.
Thursday, April 11th.—4.15 P.M., Mr. P. G. McEvedy: Rectal Pain.

UNIVERSITY OF BIRMINGHAM.
Tuesday, April 9th.—3.30 P.M. (General Hospital), Mr. G. P. Mills: Demonstration of surgical cases.
Friday.—3.30 P.M. (Queen's Hospital), Mr. Douglas Marsh: Demonstration of cases.

GLASGOW POST-GRADUATE ASSOCIATION.
Wednesday, April 10th.—4.15 P.M. (Lock Hospital), Dr. David Watson: Venereal Diseases (Female).

Vacancies

For further information refer to the advertisement columns

Aberdeen Royal Hospital for Sick Children.—Hon. Asst. Surgeon to Ear, Nose, and Throat Dept.

Aberdeen Royal Infirmary.—Hon. Asst. Phys. Also Hon. Jun. Asst. Surg. to Ear, Nose, and Throat Dept.

Ashton-under-Lyne District Infirmary.—Two H.S.'s. Each at rate of £150.

Birmingham, Erdington House.—Jun. Asst. M.O.'s. Each at rate of £200.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.

Burnley Municipal General Hospital.—Jun. Res. M.O. £150.

Burnley, Victoria Hospital.—H.S. and H.P. Each at rate of £150.

Buxton Clinic for Rheumatism and Allied Diseases.—H.P. At rate of £150.

Cancer Hospital, Fulham-road, S.W.—Second Asst. Path. £250.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Hon. 3rd Asst. to Out-patient Dept.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall.—H.P. At rate of £150.

Chesterfield and North Derbyshire Royal Hospital.—H.S. At rate of £150.

Chester Royal Infirmary.—H.S. £150.

Chichester, Graylingwell Mental Hospital.—Third Asst. M.O. £350.

Connaught Hospital, Walthamstow, E.—Cas. O. At rate of £100.

Coventry and Warwickshire Hospital.—Res. Cas. O. £125.

Derbyshire C.C.—Asst. Maternity and Child Welfare M.O. £600.

Derbyshire Royal Infirmary.—Cas. O. and Orthopædic H.S. £150.

Dewsbury and District General Infirmary.—H.S. £150.

Doncaster Royal Infirmary.—H.S. Also Cas. H.S. Each at rate of £175.

Dorchester, Dorset County Hospital.—H.S. At rate of £160.

Dover Royal Victoria Hospital.—Res. M.O. £180.

Dulwich Hospital, East Dulwich-grove, S.E.—Asst. M.O. £250.

Edinburgh City.—Depute M.O.H. £900.

Exeter, Royal Devon and Exeter Hospital.—H.S. At rate of £150.

Harrogate, Royal Bath Hospital.—Res. M.O. At rate of £156.

Ilford Borough.—Asst. M.O.H. £600.

Inverness District Mental Hospital.—Asst. M.O. (Pathologist). £400.

Inverness, Royal Northern Infirmary.—H.S. At rate of £100.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. to Asst. Surgeons. £120.

Italian Hospital, Queen-square, W.C.—H.S. At rate of £100

Kettering and District General Hospital.—Res. M.O. At rate of £200.

Kingston and District Hospital.—Res. Asst. M.O. At rate of £250.

Lambeth Hospital, Brook-street, S.E.—Asst. M.O. £250.

Leicester City.—M.O.H. £1400.

Liphook, Hants, King George's Sanatorium.—Asst. M.O. At rate of £200.

Liverpool Heart Hospital.—H.P. At rate of £100.

London Homœopathic Hospital, Great Ormond-street, W.C.—Surgeon. Also Asst. Surgeon. Also Two Res. M.O.'s. Each £100.

London Hospital, E.—Paterson Research Scholar in Cardiac Dept. £400.

London Jewish Hospital, Stepney Green, E.—Res. M.O. and H.P. At rate of £150. Also H.S. and Cas. O. Each at rate of £100.

Lowestoft Borough.—Consultant Obstetrician. 3 gns. each consultation.

Manchester, Ancoats Hospital.—Res. M.O. At rate of £150.

Manchester, Withington Hospital Institution and Crumpsall Hospital Institution.—Jun. Asst. M.O.'s. Each at rate of £200.

Margate, Royal Sea Bathing Hospital.—H.S. At rate of £200.

Metropolitan Hospital, Kingsland-road, E.—Sen. H.P. and H.S. Jun. H.P. and H.S. Also Cas. O. Each at rate of £100.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Res. M.O. Also Out-Patient M.O. At rate of £150 and £125 respectively.

National Hospital, Queen-square, W.C.—Res. M.O. £200. Also Hon. Surg. Asst., Asst. Surg., Asst. Phys., and Anæsthetist.

National Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. 40 gns.

Newark General Hospital.—Res. H.S. £175.

Newcastle-upon-Tyne Royal Victoria Infirmary.—Sen. Accident Room H.S. £150.

Norwich, Norfolk and Norwich Hospital.—H.S. £120.

Nottingham General Hospital.—Second Cas. O. At rate of £200.

Preston, Sharoe Green Hospital.—Sen. Asst. Res. M.O. At rate of £150.

Princess Beatrice Hospital, Earl's Court, S.W.—Two Hon. Anæsthetists. Also Hon. Clinical Assts.

Queen Mary's Hospital for the East End, Stratford, E.—Director of Pathology and Lyle Research Scholar. £750.

Queen's Hospital for Children, Hackney-road, E.—Asst. Phys.

Reading, Royal Berkshire Hospital.—Hon. Surgeon. Also H.P., H.S., H.S. to Ophth. and Ear, Nose, and Throat Beds Depts. Also Cas. O. Each at rate of £125.

Royal College of Surgeons of England.—Examiners.

Royal Masonic Hospital, Ravenscourt Park, W.—Res. Surg. O. At rate of £250.

St. Andrew's Hospital, Devons-road, E.—Asst. M.O. £250.

St. Bartholomew's Hospital, E.C.—Chief Asst. to X ray Diagnostic Dept.

St. John's Hospital, Lewisham, S.E.—Res. M.O. £200. Also Two Res. H.P.'s and Cas. O.'s. Each at rate of £100.

St. Leonard's Hospital, Hoxton-street, E.—Res. Med. Supt. £1000.

St. Mary Islington Hospital, Highgate Hill, N.—Asst. M.O. £250.

St. Mary's Hospital, W.—Med. Reg. (two vacancies). £200.

St. Neots, Three Counties Hospital.—Med. Supt. £1000.

St. Nicholas Hospital, Plumstead, S.E.—Asst. M.O. £350.

Sheffield, Jessop Hospital for Women.—Res. M.O. At rate of £150. Also H.S. and Res. Anæsthetist. At rate of £100.

Sheffield Royal Infirmary.—Asst. Aural and Ophth. H.S. At rate of £80.

Southend-on-Sea General Hospital.—H.P. and Cas. O. Each at rate of £100.

Sutton and Cheam Hospital.—Sen. Res. M.O. At rate of £150.

Swanley Hospital Convalescent Home, Parkwood.—Res. M.O. At rate of £200.

Truro, Royal Cornwall Infirmary.—H.S. £170.

Violet Melchett Infant Welfare Centre, Wellington-street, S.W.—Asst. M.O. At rate of £100.

Weston-super-Mare General Hospital.—Res. H.S. £150.

West London Hospital, Hammersmith, W.—Hon. Asst. Anæsthetists.

West Riding of Yorkshire County Council.—School Med. Inspector. £500.

West Suffolk County Council.—Asst. County M.O., and Asst. School M.O. £500.

Willesden General Hospital, Harlesden-road, N.W.—Hon. Anæsthetist. Also Hon. Physio-therapeutist.

Woolwich and District War Memorial Hospital, Shooter's Hill, S.E.—Hon. Laryngologist. Also Surg. Reg. £100.

Worksop, Victoria Hospital.—H.S. At rate of £160.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Wivenhoe, Essex; Stromness, Orkney; Twickenham, Middlesex; Stonehaven, Kincardine; and Turriff, Aberdeenshire.

NOTES, COMMENTS, AND ABSTRACTS

WOMEN WHO EARN

"Careers and Openings for Women"[1] is described as "a guide for girls and young women in settling the choice of a career." A more apt description would have been "A treatise on social life, more especially for the guidance of parents and their daughters." Part I. is a survey of women's employment, and Part II. a discussion of careers and prospects conveniently subdivided into chapters on prospects for girls leaving school respectively at 14, 16, 18, and over 18, for university graduates, and for exceptional girls. In the first three chapters of Part I. clear statements are to be found on the need for women to work, the opportunity for women to work, and the difficulties of women's work. Parents should realise, even if their daughters do not, that to-day most young women have to seek work.. One woman in every five must expect to continue to work all through her adult life whether she marries or not. The other four will normally marry and then either toil as hard, or harder, than before without defined payment, or will find themselves with leisure as well as responsibility. In the chapter on the difficulties of women's work, a sympathetic picture is given of the unmarried woman with family claims who has "ceased to be young." It is noted with satisfaction that the medical profession does not observe the custom of paying women less than men, and that the prejudice against women in this work has been largely overcome save in the matter of hospital appointments. The three useful appendices contain (1) a summary of the openings and trainings for women arranged in alphabetical order; (2) professional societies and trade unions; (3) an account of the Women's Employment Federation. A bibliography of seven pages is appended, and the index is a good one. In the paragraph on medicine as a career in Appendix 1, the length of training is set out as 5 to 6 years; this is somewhat optimistic, 5½ years being the extreme lower limit. Had the list of professional societies and trade unions in Appendix 2 been complete with the addresses of the bodies mentioned, the book would be even more valuable than it is.

PHYSICAL EDUCATION

A PRACTICAL summary of physical re-education covers all the important aspects of the subject.[2] Miss Rathbone begins with a review, clearly and simply illustrated, of the anatomy and mechanics of joint action and the physiology of the neuromuscular system. Faulty development due to pain, overwork, infection, and trauma is next dealt with. Then comes the chief section on reconstructive physical education. Exercises are classified according to their effects: general; on joints; for muscle tone; for group muscles. The exercises are well chosen, but the line illustrations are almost too minute to be of much assistance. Some orthopædic lesions are then mentioned, and the book ends with the treatment of mental maladjustments and some school problems.

The section on mental work is well reasoned, and this aspect could with advantage arouse more interest in this country. The idea that mental disease is often accompanied by physical symptoms (and can be helped to a certain extent by the treatment of these as regards circulation, relief of muscular tension, and so forth) is sound, and where experiments to this end have been made here they have yielded good results. The author's rational insistence that the gymnast need not know all about the case, but should treat it from a fresh and purely physical angle, is also sound. Masseuses who have worked in mental homes often complain that they have not the doctor's advantage of psychological knowledge. They forget that they have their own domain, and that to approach the patient as a physical, not a psychological, helper often simplifies the situation. The chapter on school problems reveals a sensible understanding mind, combining a good observation with a sound knowledge of life.

ERGOTOCIN.—Dr. H. W. Dudley and Dr. Chassar Moir point out that the isolation in crystalline form of a pure active principle derived from ergot by American workers, to which we drew attention last week (p. 758), was recorded only as a footnote to their paper. It is not therefore this crystalline substance, but a less pure product, which is referred to in their article as being made in large quantities by the Eli Lilly Company under the name of ergotocin.

Appointments

BACH, F. J., D.M. Oxon. [illegible], Consulting Cardiologist to the [illegible] Clinic.

BANHAM, A. R., M.B. Camb., F.R.C.S. Eng., Hon. Assistant Surgeon to the Northampton General Hospital.

BROOKS, W. D. W., B.M. Oxon., M.R.C.P. Lond., Physician in Charge of Out-patients at St. Mary's Hospital, London.

CALTHROP, G. T., M.D., D.P.H., D.M.R.E., Additional Hon. Radiologist to the Princess Beatrice Hospital, London.

DENNY-BROWN, D. E., M.B. N.Z., D. Phil. Oxon., M.R.C.P. Lond., Assistant Physician to the National Hospital, Queen-square, London.

DONALD, CHARLES, Ch.M. Aberd., F.R.C.S. Eng., Hon. Surgeon to the Hospital for Sick Children, Great Ormond-street, London.

FICKLING, B. W., M.R.C.S. Eng., L.D.S., Hon. Assistant Dental Surgeon to the Royal Dental Hospital of London.

FREWER, E. G., M.B. Camb., Resident Medical Officer to the City of London Maternity Hospital.

JENKINS, J. A., M.B. Glasg., Medical Superintendent of the District Mental Hospital, Larbert.

KELLEHER, W. H., M.D. Irel., D.P.H., Deputy Medical Superintendent (Grade II.), at the Southern Hospital, L.C.C.

LEE, R. O., M.B. Camb., F.R.C.S. Eng., Hon. Surgeon to the Northampton General Hospital.

LIGHTWOOD, REGINALD, M.D., M.R.C.P. Lond., Hon. Physician to the Hospital for Sick Children, Great Ormond-street, London.

MANDERSON, H. D., M.B. Glasg., Medical Registrar to the Out-patient [illegible]ster Royal Infirmary.

PUNCH, A. LISI [illegible]., Physician to the Hospital for [illegible]

SCOTT, GORDON, M.R.C.S. Eng., Assistant Resident Medical Officer to the City of London Maternity Hospital.

SEARS, W. G., M.D., M.R.C.P. Lond., Deputy Medical Superintendent (Grade II.), at the St. Charles' Hospital, L.C.C.

Manchester Northern Hospital.—The following appointments are announced:—

- DON, C. S. D., M.D. Aberd., M.R.C.P. Lond., Hon. Physician;
- DONALD, H. R., B.M. Oxon., M.R.C.P. Lond., Hon. Physician;
- GUTHRIE, SYLVIA, M.D. Manch., M.R.C.P. Lond., Hon. Assistant Physician for Children;
- HOLT, R. L., M.B. Manch., F.R.C.S. Eng., Hon. Assistant Surgeon;
- WATKINS, K. H., M.S. Lond., F.R.C.S. Eng., Hon. Assistant Surgeon;
- GERRARD, E. A., M.D. Victoria, M.C.O.G., Hon. Assistant Gynæcological Surgeon; and
- ARCHER, G. E., M.B. Manch., D.L.O., F.R.C.S. Edin., Hon. Aurist and Laryngologist.

Certifying Surgeons under the Factory and Workshop Acts: Dr. W. E. LOCK (Desborough, Northants); and Dr. R. A. FAWCUS (Chard, Somerset).

Births, Marriages, and Deaths

BIRTHS

ALEXANDER.—On March 24th, at Gillingham, Dorset, the wife of B. W. Alexander, M.R.C.S. Eng., of a daughter.

BANKS.—On March 31st, at 56, Gurney-drive, Hampstead Garden Suburb, to Mary, wife of A. Leslie Banks, M.D. —a son.

MARRIAGES

HILLABY—COLLINS.—On March 23rd, at Bournemouth, Hubert Hillaby, M.R.C.S. Eng., Bournemouth, to Mrs. Frances Mary Collins, of Canford Cliffs.

DEATHS

ROACH.—On March 25th, at sea, suddenly, Surgeon-Captain Sidney Roach, M.R.C.S. Eng., R.N. (retired), of Brading, Isle of Wight, aged 61.

WILLIAMS.—On March 25th, at a nursing-home, Alfred Williams, M.D. Glasg., Sussex-square, Brighton, late of Pendleton, aged 73.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

II *

Type II. Pneumococcal Pneumonia

Type II. pneumonia is more severe than Type I. and has a higher mortality. It attacks the adult; it is not so "classical" clinically; it is usually accompanied by profound toxæmia; and it less often ends in a crisis. Out of Cecil's 4310 cases[21] of pneumonia, 991 (23 per cent.) were due to Type II. pneumococcus—46 per cent. of these being under forty years of age. Cole[9] in 1918 gave an incidence of 29·3 per cent., and Park[10] of 15·6 per cent., while Blake[7] reported 13 per cent. in 606 cases. Dible's[12] collected series showed a higher incidence (31·4 per cent.), and the Glasgow statistics[13] for 1930–32 one higher still (35·5 per cent.). The seasonal incidence differs little from that of Type I.

The death-rate (as in Type I.) seems to be lower in this country than in America. Thus the mortalities recorded for untreated Type II. pneumonia by Cecil[21] (441 cases), Park[10] and Cole[9] are, respectively, 48·8, 30, and 28·8 per cent., whereas Cruickshank[13] reported a death-rate in the Glasgow series of 21·5 per cent., and the recent Medical Research Council[14] gave 27 per cent. It is noteworthy that bacteræmia is far commoner in this type: in Cecil's cases it was found in 29·7 per cent. of Type I., but no less than 51·5 per cent. of Type II. There are fewer local complications however. Thus empyemata developed in 6·5 per cent. of Type I., and only in 3·8 per cent. of Type II. In this country Christie[22] has drawn attention to the high incidence of bacteræmia in Type II. infection—28 positive blood cultures in 51 cases.

Only 13 of our cases were Type II. infections, giving a low incidence of 9·5 per cent.:—

Age.		Cases.	Age.		Cases.
10–19	....	1	40–49	....	1
20–29	....	3	50–59	....	2
30–39	....	4	60	....	2

Five of these patients died.

The temperature was not so high and fluctuated more than in Type I., but the patients were nevertheless more ill. They appeared pale, toxic, and disinclined to move; this listlessness was in conspicuous contrast to the "vigorous" reaction seen in Type I. Chart 4 (that of a patient admitted on the sixth day in a very toxic condition) shows only moderate fever, but the pulse and respiratory rate were 152 and 48. Only three of the cases terminated by crisis; none had an empyema.

Agglutinins.—Systematic examination for agglutinins was made in 10 cases, and the results agreed with our findings in Type I. infection—i.e., no agglutinins were detected until resolution was in progress. Agglutinins persisted throughout the period of resolution. In 3 fatal cases none was detected before death, but in these there was no evidence that resolution was occurring.

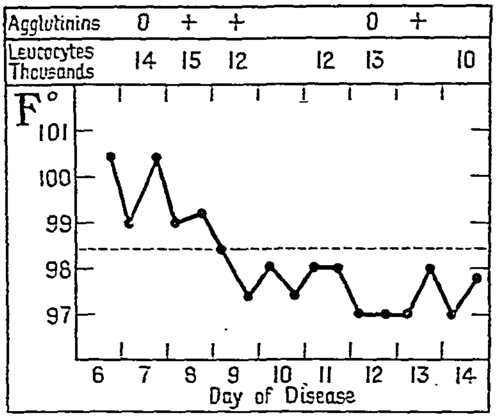

CHART 4.—Type II. pneumonia in a male aged 42.

Leucocytes.—The average leucocyte figure for this type of pneumonia was somewhat lower than in Type I. Our most favourable and uncomplicated case had the high initial leucocytosis of 33,000. The fatal cases had initial leucocyte counts of 18,000, 16,000, and 12,000. The usual figures ranged between 15,000 and 18,000. It was also noted that the fall in white cells was delayed long after the cessation of fever. Four of the patients who recovered still showed a leucocytosis a week after the temperature had become normal, although no complications were found.

Blood culture.—In 4 cases this was done and found to be negative; one of these patients died.

Serum treatment.—Type II. pneumonia is shown even in this short series to be a more serious disease than Type I., and it is unfortunate that none of our cases were admitted early enough to justify serum treatment. Elsewhere this has not proved so efficacious as in Type I. pneumonia, although Cecil[21] has shown a material improvement in a group of selected cases in which serum was given within the first three days. The largest series treated is that of Cecil:—

			Cases.		Mortality.
Treated	..	..	252	....	40·5 per cent.
Untreated	..	..	253	....	45·8 ,,

When treatment was confined to early cases (first three days of disease) the results were far more promising:—

			Cases.		Deaths.
Treated	..	..	21	....	3 (14·3 per cent.)
Untreated	..	..	20	....	13 (65 ,,)

Statistics compiled by Cecil from other sources show some reduction in mortality.

			Cases.		Mortality.
Treated	..	..	232	....	31·4 per cent.
Untreated	..	..	224	....	43·3 ,,

The Medical Research Council report[14] is also less encouraging concerning the response of Type II. to specific therapy :—

---

* Part I. of this paper was published in THE LANCET last week. Part III., on the Radiology of Pneumonia, will appear in the next issue.

	Cases.		Mortality.
Treated	164	....	20 per cent.
Untreated	305	....	27 ,,

At present it has not been shown that in this form of pneumonia serum has an effect which will bear statistical analysis. With or without serum it still is a serious disease.

Type III. Pneumococcal Pneumonia

Type III. infection has always been regarded as the most fatal of all. In Cecil's[8] collection of 4310 cases there were 477 due to this type—an incidence of 11·1 per cent. Cole's[9] early series gave a frequency of 13·0 per cent. The British investigators have recorded a lower incidence—Dible[12] only 3·7 per cent. in 766 cases, and Cruickshank[13] 3·6 per cent. in 1215 only. Blake, however, in a study of 606 cases showed a high incidence (20 per cent.). In our small series there were 20 cases of Type III., a percentage incidence of 15·0.

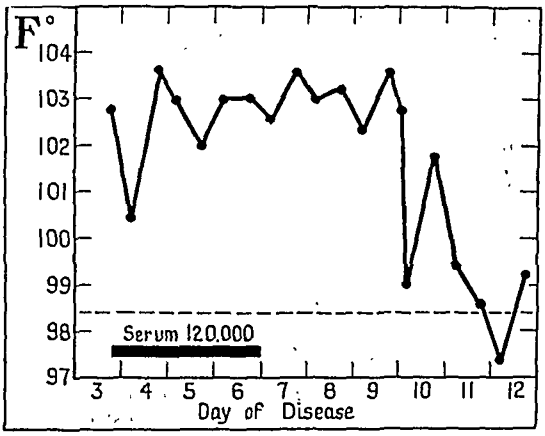

CHART 5.—Type III. pneumonia treated with Type I. serum. No specific effect.

The records demonstrate that Type III. is more likely to attack the old than the adult. Of Blake's 122 Type III. patients, only 12 per cent. were between ten and forty years of age, compared with 53·8 per cent. over forty ; whereas in his 194 Type I. patients only 19 per cent. were over forty. The case-mortality of Type III. pneumonia has been given by Cecil as 42·7 per cent., by Cole[9] as 43 per cent., by Cruickshank as 40·9 per cent. and Blake as 44·3 per cent. There is, therefore, no little agreement about the high death-rate. But while it is evident that Type III. is a most serious form of pneumonia, doubt has been cast on the virulence of the organism itself. Blake found that, irrespective of age, in 40 cases free from chronic disease the mortality was only 15 per cent. compared with 56·9 per cent. in another group of 79 who were victims of chronic disease. Blake presents good reasons for regarding Type III. pneumonia as a "highly fatal specific infective disease due, in general, not to a highly virulent organism that attacks and kills a healthy host, but rather to a debilitated host that succumbs to what is relatively a mild infection in the vigorous."

In our series of 20 Type III. infection, 15 were over forty years and 5 under. Of this group 8 died and of these 7 were over forty. Seven were relatively mild cases. The leucocytosis was found to be less than in Type I., the white cell count ranging between 10,000 and 15,000 per c.mm. In cases where the agglutinin content was systematically followed, it was found that in this infection also the agglutinins appeared as resolution phenomena, usually recognisable after a crisis or lysis, rather than coincident with or preceding it.

Of the 8 fatal cases 5 suffered from a chronic chest infection ; these patients were closely questioned and all asserted that they had expectorated a suppurative sputum for years. Four had emphysema and one was a chronic alcoholic ; two exhibited leucopenia. We consider that in this group the deaths were due to the abnormal condition of the chest as much as to the virulence of the pneumococcus.

One of our patients with Type III. pneumonia, a female aged 37, was erroneously regarded as a Type I. infection and was given serum on the third day of disease. In all 120,000 units of serum, and no specific effect was obtained (Chart 5). This case provides an excellent control as to the duration of passively introduced agglutinins. The heterologous agglutinin Type I. was detected within a few hours of the administration of the first 20,000 units of serum (10 c.cm.) and was detectable up to four days after the last dose. The heterologous Type II. agglutinin was not detected until after the second dose of serum had been given and it disappeared somewhat earlier than the Type I. Table VI. shows the fate of the passively introduced agglutinins as well as the development of the natural agglutinins.

TABLE VI.—*Case of Type III. Pneumonia treated with Type I. Serum*

Day of disease ..	3	4	5	6	7	8	9	10	11	12

,, III. ,, ..	0	0	0	0	0	0	0	0	+	+

Group IV. Pneumonia

About 30 per cent. of all pneumonias are attributed to "Group IV." Cecil puts the incidence at 33·8 per cent., Cole at 24·6 per cent., Dible at 30·6 per cent., and Cruickshank at 24·7 per cent. The mortality varies from 8·6 per cent. (Glasgow, 1930–32) to 31·0 per cent. (Cecil's Bellevue series). There is little predominance in any decade although it is responsible for pneumonia in children far more commonly than is the Type I. or II. pneumococcus.

In our series, 49 cases fell into this category, and 7 of the patients died, giving a mortality of 14 per cent. The number over and under forty years of age were 17 and 32 respectively, and age appeared to have the same influence in this group as in the specific types. Thus a young subject often showed a high fever, ending with an early crisis and rapid resolution, while the elderly were more likely to have a minor fever, with grave toxæmia, termination by lysis, and delay in resolution.

Anomalous and Mixed Infections

Under this heading we have collected 12 cases which illustrate the difficulty sometimes encountered in making certain of the nature of the primary infecting organism. Because this study is based on cases investigated in a routine manner, with examinations including blood and serum tests as well as typing of sputal cocci, we have come across anomalies and phenomena, some of which have not previously been recorded, and these emphasise the fallibility of sputum examination alone. The series of 12 cases has demonstrated three sources of error.

1. Cases diagnosed as pneumococcal pneumonia which later developed a streptococcal complication (6).
2. Cases diagnosed from the sputum as type infections which later proved to be due to a different type (2).

3. Cases in which there was indisputable evidence that the pneumonic process was due to infection with more than one type (4).

1. *Pneumococcal pneumonia with streptococcal complications.*—Table VII. summarises the salient features of these cases:—

TABLE VII.—*Pneumococcal Pneumonia with Streptococcal Complications*

Case.	Type pneumococcus and prevalence in sputum.	Agglutinins in blood.	Streptococcal complications.	Remarks.
1	Type I. 50 %	Nil	Nephritis.	Strept. in urine.
2	,, I. 30 %	,,	Bacteræmia.	—
3	Gr. IV. 30 %	N. t.	Empyema.	*Hæmophilus influenzæ* in sputum.
4	Type II. 50 %	Nil.	,,	
5	Gr. IV. 80 %	N. t.	,,	
6	Type I. 20 %	Type I.	Meningitis.	—

Gr. = group. N. t. = Not tested.

Each of them at the onset presented definite clinical signs of a pneumonia of lobar distribution—a finding which, supported by the discovery of reasonable numbers of pneumococci in the sputum, is usually sufficient for a confident diagnosis of pneumococcal pneumonia. Yet the subsequent course of the disease made it very doubtful whether the pneumococcus was the primary or main cause of the illness.

It is conceivable that a pneumococcal pneumonia may be capable of lighting up a streptococcal complication. This, we can conclude, is what happened in Case 6, for during the phase of recovery from the pneumonic part of the illness specific type agglutinins were detected in the blood. On the other hand, Cases 1, 2, and 4 never throughout their illness manifested any type agglutinins. It is probable that had Group IV. agglutinins been looked for in Cases 3 and 5 they also would not have been found.

One can only conclude that during influenzal periods, when most of these cases occurred, it is extremely difficult to say with certainty which of the organisms in the sputum is the cause of a pneumonic process. Experience shows that streptococcal bronchopneumonia is the commonest sequel of influenza. Our cases tend to emphasise the difficulty of diagnosis from sputum alone, and to suggest that pneumococcal antiserum should be given with caution during an influenzal epidemic.

2. *Cases diagnosed as a type infection which later proved to be of different type.*—The two cases classed under this heading are not simply examples of error in typing the sputal coccus, for the direct test was confirmed by mouse inoculation and culture. Both cases had plentiful Group IV. pneumococci in the sputum and both developed strong specific type agglutinins in the blood-serum during the recovery and resolution period, the one Type I. and the other Type III. From our previous experiences we can only conclude that these cases were really Type I. and Type III. infections despite the indeterminate content of the sputum. It is probable that this kind of case is rare. Both were extremely mild and there was very little expectoration.

3. *Cases in which the sputum contained more than one type of coccus.*—It is usually believed that in any particular case pneumococcal pneumonia is caused by only one strain of pneumococcus. We met with 4 cases, however, in which the sputum contained two types of cocci, and in 3 of these the blood-serum during the resolution period contained strong agglutinins for both cocci. This we consider is indisputable evidence that both types of cocci were concerned in the pneumonic process. The facts concerning the four cases are summarised in Table VIII.:—

TABLE VIII.—*Cases with Two Types of Cocci*

Case.	Cocci in sputum.	Agglutinins in blood.	Remarks.
6	Types I. and II.	Types I. and II.	—
7	,, I. and II.	,, I. and II.	Sterile pleural effusion.
8	,, I. and III.	,, I. and III.	—
9	Type III. and Group 4.	Not tested.	Died.

It is of interest that in Case 8 the Type III. cocci were not isolated from the sputum until late in the disease. Their presence had not been suspected until a test during the resolution period showed that the serum contained Type III. as well as Type I. agglutinins, and re-examination of the sputum by platings from the peritoneal cavity of a mouse then revealed the hitherto unsuspected Type III. coccus. This case is instructive; it is conceivable that a pneumonia due to Type I. can be overcome with serum, and yet the patient perish from Type III. toxæmia.

Laboratory Estimates of Immunity

The basis of the specific treatment of lobar pneumonia is the administration of a serum whose potency is estimated by its ability to protect mice against living and virulent pneumococci. Any simple method of demonstrating that a human serum contains the same protective substances should be of value both for prognosis and as an indication for continuing or stopping serum therapy. It is unfortunate that at present the only reliable methods for estimating the potency of an antipneumococcal serum involve the use of large numbers of mice as well as a delay of several days. Such methods are not therefore applicable to the control of human cases except in the academic study of a small series. The antibodies which may be studied include agglutinins, precipitins, and substances which will bring about the protection of a mouse. The general resistance is indicated by the leucocyte count.

Leucocyte count.—As already stated, we have found that a daily leucocyte count is very valuable for estimating general resistance and prognosis. Initial high counts (20,000–30,000) are obtained in all cases that are likely to recover; a normal count or a leucopenia in the invasive phase of the pneumonic process is an ominous sign. Coincident with the crisis there should be a dramatic fall in the leucocytes; when this does not take place complications may be anticipated.

Agglutinins.—It has often been pointed out that the agglutinin titre is not a reliable indication of the true protective power of the serum as estimated by the mouse-protection test. This inconstancy was first described by Avery, Chickering, Cole, and Dochez[23] in 1917, and has been confirmed by, among others, Parish,[24] who found a discrepancy between the agglutinin content of three samples of serum and their power of protecting mice. Yet, Cole and his colleagues,[23] in 1917, in their study of the agglutinin content of empyema fluids and the blood-serum of animals and human beings heavily infected with pneumococci, found that agglutinins were absent where infection was overwhelming, and attributed their absence to neutralisation and inhibition of pneumococcal antibodies by soluble substances produced by the bacteria themselves. They believed that the "specific soluble substance" of the pneumococcus was capable, when excessive, of neutralising all types of pneumococcal antibodies.

The test for agglutinins is easily performed. Take three drops of the patient's serum and add to each drop a small quantity of a thick emulsion of the specific type pneumococcus: agglutination occurs rapidly and can be observed with the low power of the microscope. This simple qualitative detection of agglutinins is all that is required; there is no advantage in performing a quantitative test. We have systematically studied the agglutinin phenomenon at various stages of the disease and have also attempted to use the agglutination test as a basis for serum dosage.

Sabin,[20] using a staining method, found that agglutinins for the homologous organism were quickly absorbed after injection of serum and were not detectable in the peripheral blood until either an excess had been passively administered or the patient had started actively to make his own. The heterologous agglutinins, on the other hand, were easily detectable soon after the injection of serum. Sabin claimed therefore that after serum injection disappearance of agglutinins indicated the specific type of the organism, and also that serum should be given until agglutinins were detectable. With these conclusions, as pointed out in Part I., we have been unable to agree. The detection of passively introduced agglutinins in the peripheral blood has appeared to be purely a resultant of the amount introduced rather than the amount absorbed. The following titration will make this clear:—

The agglutinin content of a given sample of Felton's serum was found to be: Type I., 1 in 1200, Type II., 1 in 80, by the macroscopic method, and by the more sensitive microscopic method Type I., 1 in 2400; Type II., 1 in 320. Dilutions of the Felton's serum were made with fresh normal human serum. When 10 c.cm. of serum are injected intravenously they are promptly diluted 500 times by the volume of the circulating blood. Unless therefore an agglutinin titre exceeds 1 in 500 it will not be detectable when 10 c.cm. of serum are injected.

Owing to the low titre of the Type II. agglutinins it is not often possible to detect them in cases of Type I. pneumonia unless a considerable volume of Felton's serum has been used.

During our investigations we have performed some 3000 agglutinin tests and conclude that agglutinins are abundantly produced in association with the process of resolution after the crisis. Before the crisis they are not detectable, and after it they are no indication that a case will be free from a relapse or complication. We do not regard them as any evidence of the sufficiency of serum therapy, and they are certainly not an indirect indication of type as suggested by Sabin.

Summary and Conclusions of Parts I and II

The examination of a case of pneumonia nowadays is incomplete without the typing of the infecting pneumococcus; we agree with Cecil that it is now far more important to know the type of pneumococcus in a case of pneumonia than it is to know what organism of the *coli*-typhoid group is responsible for an enteric fever. Typing of the pneumococcus has entered the field of necessary clinical pathology.

Gradually data are accumulating which will help to give each type infection a defined clinical picture. We have been impressed with the distinctiveness of some of our cases, and an attempt has been made, in describing our findings, to show the features typical of each. Further work is necessary in this country, for type-incidence has not been studied here as extensively as in America.

While it is now possible to type a pneumococcal sputum within two to three hours, and sometimes directly within a few minutes with reasonable accuracy, it must be emphasised that this can never be regarded as a bedside procedure. Much experience as well as good laboratory equipment are essential. It is unfortunate that attempts to type the sputum in the earlier stages of pneumonia are often far more difficult than in the later stages, and this is an important practical point. At the sixth or seventh day the sputum often yields a pure culture of the pneumococcus and the typing is easy; but during the first and second day—at the time when specific treatment gives best results—the sputum is sometimes less abundant. Furthermore, we have recorded cases in which there was reason to believe that the pneumococcus in the sputum was not the organism responsible for the underlying lung infection, and we have also described cases in which two distinct types seemed to be responsible. Again, some patients with all the signs of pneumonia produce a sputum devoid of pneumococci. Although these and other difficulties will arise from time to time, the determination is usually not difficult, and the organism found in the sputum will probably be the one responsible for the pneumonia.

Serum therapy in Type I. pneumonia has unquestionably proved, within certain limitations, to be both specific and effective. Even our small series convinces us of its advantages—and we deliberately selected the cases we regarded as the most serious. All are agreed on the beneficial effect obtainable when Type I. serum is given within the first three days of the disease, and some have indeed claimed an abortive effect if serum is given thus early. Although it would be bold to claim that serum is responsible for a crisis when administered later than the fifth day, we included among the more severe cases three whose condition we held to be desperate on the sixth day, and clinically we could only conclude that they too were benefited. The possibility of serum sickness should not prevent the giving of serum to a patient in need of the exploitation of every remedy. Our incidence of serum sickness has been somewhat high, but this was probably due to the particular batch of serum employed.

It would be a great gain in practical therapeutics if patients with Type I. pneumonia who need specific therapy to realise a crisis could be readily distinguished from those who will come safely through without any specific measures. Unfortunately there is no single test that we can rely on for this purpose. To treat all patients showing lobar consolidation with Felton's serum on the chance of striking a Type I. or II. infection is unnecessary as well as costly; indeed, such a practice might do more harm than good. It is also unwise and unnecessary to treat all Type I. infections with serum, for we know that the mortality of the untreated case is low. Hence if the case shows favourable features we are justified in withholding specific measures, and we have come to regard the following as favourable criteria: an age under forty; freedom from past chest disease and signs of bronchitis and emphysema; a normal blood pressure; and a good initial leucocytosis. On the other hand, if the patient is over forty, has long-standing chest disease, shows arterial hypertension, or has a leucocytosis below 15,000, we should feel that serum therapy was desirable. Signs of a severe infection, such as massive consolidation, cyanosis, or profound toxæmia, would always call for specific measures, irrespective of the patient's age. Mortality in Type I. pneumonia is much higher at ages over forty, and it would be a good practice to give serum to everyone above that age suffering from such infection, even though the state at the onset was reasonably good. It is often impossible during the first two or three days to forecast the course, and unfortunately from the standpoint of active therapy this is the period when an accurate prognosis is most needed.

Our experience shows that arterial hypertension adds much to the gravity of pneumonia, while chronic respiratory disease is another important factor, especially in Type III. infections. In Type I. or II. pneumonia with either of these complications there is *accordingly a relatively greater need of serum.*

In judging the progress of a pneumonia, a simple leucocyte count seems to us to be the most informative test, provided it is done repeatedly. Thus an initial count of 20,000–30,000 per c.mm. carries a good prognosis, but leucopenia or a normal count in association with signs of pneumonia is of very grave significance. A sudden fall in leucocytes usually accompanies a crisis and heralds a convalescence free from complications. On the other hand, a leucocytosis persisting in spite of a crisis, a normal temperature and pulse, is usually the forerunner of a complication.

The facilities at our disposal did not allow us to perform daily blood cultures, but cases in which an initial culture was positive did not appear to have a less favourable outcome than those in which it was negative. As to the phenomenon of agglutination which many observers have used to assess the amount of serum required, we have found no evidence that it is useful for this purpose. This reaction was to us of little clinical value. It is well known that the agglutinin content is no reliable guide to the protective power of a pneumococcal serum, and in our experience the presence of agglutinins is no indication that a case will be free of complications.

SEPSIS AND THE SKIN *

By John T. Ingram, M.D., M.R.C.P. Lond.

PHYSICIAN IN CHARGE OF THE SKIN DEPARTMENT, GENERAL INFIRMARY, LEEDS; LECTURER ON DISEASES OF THE SKIN, UNIVERSITY OF LEEDS

Septic affections of the skin are worthy of more attention and better treatment than is generally bestowed upon them. We usually know the cause of these troubles which are completely displayed to our view, and we might therefore expect to be able to apply direct and effective treatment. Instead, we find that fashion and fad often govern much of our practice, and there are as many medical and quack remedies for such simple infections as boils and impetigo as we might expect for an obscure and hopeless disease of unknown ætiology. This is not greatly to the credit of our profession. Like many other matters, these common dermatological ills of everyday practice are brought too little before the student in training by his teachers, they rarely get beyond the casualty departments of hospitals, and when they have become serious they often pass straight to the surgeon whose dermatological knowledge is not his strongest claim to fame.

I wish first to draw attention to a few practical points in regard to the common simple skin infections, and later to try and throw a little light on some of the more complicated and difficult infective dermatoses.

Simple Infections

Impetigo.—A superficial streptococcal infection is often secondary to parasites, particularly to pediculosis capitis, in children. It may be superimposed on some itching dermatosis, or may be dependent upon fissures or other foci of streptococcal infection. These should be sought first and not last. *Impetigo is a vesicular and bullous eruption, and it is* therefore irrational to treat it with a white precipitate or any other ointment. An ointment cannot intermingle with the infected fluid, and will ride on that fluid instead of sitting on the infected surface. Treatment should be by means of a paste which absorbs the infected fluid, and so comes into direct contact with the infected surface. The paste should contain a mild antiseptic and a little salicylic acid to dissolve scabs, and such a preparation as the following will cure impetigo in a few days—far more readily than any other measure and with the minimum of effort: ℞ Hyd. Ammon. gr. x., Acid. Salicyl. gr. x., Zinc Oxide gr. cxx., Amylum gr. cxx., Paraff. Moll. ad oz. i.

Fissures are the seat of streptococcal infections, but fissures are rarely primary. When they are so, they readily respond to simple cauterisation with silver nitrate or chromic acid, provided this is done thoroughly. Fissures are, in the great majority of cases, secondary to eczema or other skin disorders, and disappear without any specific treatment for the fissures if the underlying eczema is treated. Thus, a little white precipitate in a tar ointment or X ray therapy will more commonly clear, and clear permanently, the fissuring behind the ears, in the flexures of joints, between fingers, and on the palms, than will cauterisation.

Fissures between the toes are almost invariably due to ringworm infection, and the chronic eczematisation which often accompanies that infection. Treatment to be effective must—and need only—consider such mycotic and eczematous disease. Whitfield's benzoic and salicylic and, later, tar ointments are indicated here.

Fissures about the angles of the mouth and nose mean intranasal, sinus, or dental infection or irritation, in the great majority of cases. Sometimes, when thorough examination reveals no such infection, it will be found that such fissuring has been dependent upon an unerupted wisdom tooth. It must not be forgotten, however, that chronic fissures at the angles of the mouth are often symptomatic of gastric and blood diseases, particularly of achlorhydric anæmia. Fissures are symptomatic and not primary, in spite of the fact that they can themselves give rise to very serious secondary troubles, as lymphangitis, adenitis, abscesses, elephantiasis, erysipelas, and septicæmia.

That erysipelas is a streptococcal dermatitis is certain, but whether there is a specific erysipelas streptococcus responsible for those spontaneous, often serious, contagious cases which sometimes give rise to epidemics as opposed to the erysipelas which is obviously secondary to other streptococcal lesions is not clear. That the picture of erysipelas, often recurrent and eventually giving rise to some lymphatic blockage and elephantiasis, can arise secondary to a streptococcal fissure infection, to intranasal or other underlying streptococcal disease and to surgical operation, is certain. This type, usually quite mild, but occasionally severe and markedly pyrexial, does not appear to be so contagious or to give rise to epidemics. The old treatment by ichthyol locally, eliminative measures, and antiserum therapy would appear to have justified itself.

---

* Based upon lectures given at a post-graduate demonstration at Leeds (March 12th, 1935) and at Grimsby (March 20th, 1935).

The treatment of cellulitis and abscess formation does not call for comment from me except to recall the value, in the later stages, of general ultra-violet light therapy, which is not practised sufficiently. The very great value of cod-liver oil to restore the balance between connective tissue and epithelium should be stressed ; nothing favours the control of granulation tissue—probably by epithelial stimulation—and the efficient healing of granulating wounds (especially when tendons are exposed) as the application of this drug itself, or in glycerin, or in a simple ointment. In this connexion also radiant heat therapy and occlusive elastoplast bandages have a place.

Whitlows.—Dry heat is always better than wet, macerating heat, and finds an important place in the treatment. The minimum of surgical interference is desirable ; extensive incisions, squeezing, probing, scraping, dilatation with sinus forceps, cauterisation, packing with antiseptics and such violent, primitive, and barbaric measures, which can be witnessed daily in most casualty departments, should be forbidden. Radiant heat, occasional swabbings with a *mild* antiseptic lotion, rest, and a simple and reasonable incision when the lesion is pointing is indicated. If fomentations are employed, they should be applied every ten minutes for an hour, and should not be covered with oiled silk, which favours maceration. Such a session of fomentations—perchloride fomentations preferably—may be repeated once or twice a day, the part being swathed in sterile, dry dressings between such treatments. Soaking in hot lotions is desirable, however, when such lesions are discharging ; occasional immersion for short periods in a peroxide bath may be permitted, but should not be continued for long.

Septic perionychia is characterised by the painful bolster swelling of the nail-fold from which pus can be expressed. It must be differentiated from ringworm and monilia infections, which are dry or almost dry and little if at all painful. Septic perionychia should never be treated surgically ; avulsion of the nail, lateral incisions, and the turning back of a flap of nail-fold are quite unjustifiable under any circumstances. The acute phase should be treated along the same lines as a whitlow, with the addition of small doses of unfiltered X rays. The chronic affection will always respond to packing of the perionychial sac with a wisp of cotton-wool soaked in pure carbolic (it is packed into the sac by means of a match stick sharpened to a wedge-end) and subsequent X ray therapy. Apart from such treatment, the part must be kept dry and warm. One or two such treatments will suffice to cure the condition, cure being manifest in obliteration of the sac so that the nail-fold again adheres to the nail-plate.

Failure to cure the condition by such means indicates that some underlying predisposing cause of the perionychia has been overlooked and, as with fissures, perionychia is very often a secondary and not a primary condition. Predisposing causes are poor peripheral circulation, which can often be improved by thyroid therapy, and anæmia, which calls for tonic treatment. The perniosis predisposes partly by reason of impaired nutrition, but mainly because of the degree of chronic œdema of tissues which accompanies it and the hyperidrosis, both tending to devitalise the skin and favouring separation of nail-fold from nail-plate. It is natural, therefore, that occupations which involve immersion of the hands in water, with similar maceration of the tissues, should also predispose to perionychia. Septic perionychia is commonly staphylococcal in origin, though it may be streptococcal or may be due to other and mixed infections.

To understand and treat the skin efficiently, we must always be prepared to read into skin manifestations the indication of some underlying local disease, or of some general constitutional derangement. It is in this way that a knowledge of skin diseases becomes invaluable to the observant physician and surgeon ; treatment becomes rational and good results are obtained. We should learn much more about our patients could we cultivate this habit, and we should find the skin not only more amenable to our attentions, but of fascinating interest and instructive.

Boils and Carbuncles

In turning to the staphylococcal infections of the skin, my suggestions for more restraint in surgical approach must become a plea for complete restraint. The pustule, the boil, and the carbuncle should never be subjected to surgical trauma, but should be nursed with a masterly inactivity throughout, rather with the physician's than the surgeon's outlook. I regard the crucial incisions, scrapings, packings, and excisions practised by my energetic colleagues with horror.

The simple superficial pustule demands to be left alone, and to be sealed-in with collodion is the best treatment. A mild antiseptic lotion as 1–2000 hydrarg. perchlor. may be swabbed round the affected part. If there is much inflammatory exudate round the pustule, or if there is some necrosis of tissue and formation of a slough, an occlusive dressing of the elastoplast type is more comfortable. In either case, the application is left in place for several days until the condition has subsided. Rest, dry heat, tonic therapy, or other symptomatic measures may be indicated.

For extensive areas of superficial pustules—so-called Bockhart's impetigo—painting with malachite-green is invaluable and causes no irritation. ℞ Hydrarg. Perchlor. ½ per cent., Brilliant Green ½ per cent., Indust. Spirit. 99 per cent. For larger boils with any considerable degree of slough and pain, dry heat, or sessions of fomentations as previously described, or better than either, compresses of carbolic in glycerin 1 in 8 may be applied.

With carbuncles exactly the same line of treatment is required, except that the patient must be at rest in bed and X ray therapy must be administered. X ray therapy is the ideal measure in the treatment of all forms of staphylococcal infection of the skin and may be used with the greatest advantage for pustules and boils, and especially for boils situated about the face and in moist flexures like the axillæ, where control of spread is difficult, and in cases of chronic furunculosis. But though we may, more often in the milder cases, choose to dispense with this measure upon occasion, we should never omit X ray treatment in any case of carbuncle, mild or severe. This has been recognised by many for years, yet surgeons continue to attack carbuncles with the knife and rarely consider this specific measure. X ray therapy should be given in fractional dosage with unfiltered X rays, one to three treatments being necessary. It is possible that staphylococcal toxoid may be a second essential weapon in this attack upon the staphylococcus, but it has not yet been put sufficiently to the test of time.

There are many minor but important points concerning these follicular infections which I should like to touch upon, though in dealing with predisposing and other factors I may seem to have left till last what should have come first. I have done that because I wished to dismiss first the local treatment, which is so important, which is the same for the whole group and which, as I have tried to stress, is allowed quite improperly and harmfully, to be surgical and interfering instead of medical and restful.

With these infections we too often concentrate upon the skin treatment, even in chronic cases, when we should be seeking and treating the cause of the chronicity. The cause may, as with streptococcal infections, be dependent upon parasitic or other skin disease, irritation or friction, maceration of the skin with natural sweat (as in the axilla) or grease (as in the seborrhœic), or maceration following employment involving contact with water or grease. Chronicity may be due to reinfection from some focus of staphylococcal infection in the nose, mouth, throat, or ears, from a perionychia or sinus. Itching and the consequent rubbing and scratching may be the cause of persistent furunculosis, and is seen about the neck, the perineum secondary to pruritis ani, and over the fronts of the thighs from the rubbing of the contents of trouser pockets. An important aggravating factor, and a cause of spread and chronicity, is fingering and squeezing of boils by the patient, and the carrying of infection to other parts of the body on the fingers. Patients should be told to leave their lesions alone, and to wash their hands in an antiseptic after touching the skin. A prescribed ritual in this matter will tend to stop the habit.

Just as I have made no mention of the use of the knife in this connexion, so I would omit reference to the hundred and one remedies recommended for the treatment of boils in the medical and lay press. I have tried to show that while their existence and advocacy does not reflect to our credit, they are likewise quite unnecessary and without serious value. That does not mean that any indications for general symptomatic treatment should be neglected; it is merely the suggestion that tin or yeast or manganese or vaccines and such-like are the cure or even the rational line of attack against which I rebel. Patients with chronic sepsis of this type are often debilitated, have mouth or nose sepsis to be treated, require attention to their diets and to gastro-intestinal function. This is particularly true of the seborrhœic who, with his greasy skin, is specially susceptible to infection, and who is particularly prone to suffer from iron and vitamin deficiency. Similarly, we must not omit to examine the urine and to review a case showing glycosuria.

Infective Seborrhœic Eczema and Sycosis

In the more complicated septic skin conditions I would suggest a direct causative relationship between these and nose, throat, and mouth sepsis. I refer to the so-called "infective seborrhœic eczema" of the head and face and "seborrhœic sycosis." Either of these may be associated with spread to other parts of the body, particularly flexures, but such spread is dependent upon the head infection and will disappear if that is cured.

In a typical case the red, glazed scalp is covered with a multitude of small green and yellow, foul-smelling pustules, readily scales, scabs, and cracks, and the greatest care in cleaning up the scalp is followed in a few hours by a fresh layer of pustules and scabs. The ears are involved and are fissured, the eyebrows are scabbed, the eyelids are red, granular, and everted, the nares and mouth are often sore and cracked. The red, sullen inflammation may spread over face and neck on to the shoulders, under the breasts, groins, axillæ, elbows, knees, always with a red, glazed, oozing, pustular, scabbed and cracked, foul, and painful inflammation. This is the complete picture, though any one part may exist alone, such as the scalp or ear affection, the blepharitis or affection of the muzzle area or of flexures. In the adult male the same condition is seen as seborrhœic eczema and sycosis involving hair margins, eyebrows, beard, and moustache. The condition occurs at any age and is often seen in quite young children and adolescents. This group is one which holds more ghosts for dermatologists than any other; they haunt him and his department often for a lifetime. They sometimes drive him to such extremes as the deliberate production of radiotherapeutic atrophy, which itself is distressing, and occasionally these patients will take their own lives, preferring death to the perpetual hell of existence under such a scourge.

The affection itself is peculiar in many features. A little consideration would suggest that it could not be a primary skin infection such as is generally believed, and none of the ideas put forward to explain the ætiology and pathology of the condition are in the least satisfying or convincing. Such patients may be given the greatest care as in-patients in hospital for months or years, and the same foul, septic, glazed, repulsive state persists or increases. That is not the behaviour of a primary skin infection, particularly a primary pyogenic infection. These patients, as a whole, and not only their skins, are particularly susceptible to infection. Thus, they have infected noses and accessory sinuses, tonsils, gingivitis, decayed and septic teeth. They also suffer respiratory and gastro-intestinal infection, but less readily than skin, nose, and throat infections. As part of the constitutional predisposition there is anæmia, often well marked, and avitaminosis and general physical debility and malnutrition. This is due, no doubt, to gastro-intestinal "seborrhœic" debility with its flatulent dyspepsia, constipation, and consequent impaired absorption.

The first essential to grasp is that this is a general and not merely a skin problem and may call for surgical, dietetic, iron, and vitamin as well as skin therapy. The second and more important fact is that the nose and throat and skin infections of head and face are not merely associated symptoms. The one is the cause of the other. The infected eczema or sycosis is directly provoked by the sinus or mouth infection. This is not a question of focal sepsis and secondary toxic manifestation; it is the direct anatomical relationship that matters, so that an infected right antrum will produce a right-sided sycosis and blepharitis, and ethmoiditis will produce an infective seborrhœic eczema of scalp, and a one-sided scalp infection will be related to an otitis media or dental sepsis on the same side. The unilateral cases are most striking, and first drew my attention to the causative relationship of the sepsis.

Surgical treatment, generally the opening and drainage of an infected antrum, is indicated as soon as the nasal or mouth sepsis is located and is usually followed by dramatic clearance of the eruption. The resistance of some patients may be so depressed that they are unable to eradicate the trouble in spite of this surgical help, and in these cases the greatest attention must be paid to diet and care of bowels; iron and vitamin therapy are necessary and the most vitalising of all measures, general ultra-violet light therapy, is given daily. By these means the most reluctant intranasal sepsis can usually be subdued, and when that is achieved the skin clears. These patients naturally require to be kept under supervision—particularly with regard to their diets, general nutrition, and health—after they are cured, for they often return to environments which would readily reproduce the old conditions and favour repetition of the round of infection.

It is interesting to note that occasionally dental or nasal infection will be directly related to the localisation and persistence of lupus erythematosus which will clear with drainage of an antrum and relapse temporarily with subsequent temporary infection of the antrum with a "cold in the head." A similar association is occasionally seen between nose and mouth sepsis and the more pustular forms of acne and of rosacea of the face. Cases which have completely resisted ordinary measures may clear dramatically when such underlying infection has been found and removed.

I have endeavoured to restrict my observations to those aspects of the subject which are of daily and practical importance, and for that reason I have made no reference to the less common pyogenic dermatoses, or to the rare toxic and allergic manifestations of focal or other sepsis.

A NOTE ON
FERRY'S MENINGOCOCCUS ANTITOXIN
IN THE TREATMENT OF ACUTE CEREBRO-SPINAL FEVER

By H. Stanley Banks, M.D. Glasg., D.P.H.
MEDICAL SUPERINTENDENT, PARK HOSPITAL, LONDON

In 1931 Ferry, Norton, and Steele[1] found that filtrates from young cultures of the four recognised Gordon types of the meningococcus contain extracellular toxins specific to the four types, as well as a toxin common to all types; and, further, that animals injected with the toxins of the four types develop, respectively, antitoxins specific to the homologous toxins, as well as antitoxins which will neutralise the heterologous toxins. These workers claim that a polyvalent antitoxin can be prepared containing immune bodies specific to the four individual toxins.

Later, Ferry[2] showed that such an antitoxin, prepared from the horse, protected guinea-pigs prophylactically and therapeutically against fatal doses of live cultures. It was also shown that regular antimeningococcic serum prepared as an antibacterial serum by immunising the horse with the same live cultures of the four Gordon types failed to protect in like manner when used either as a prophylactic or therapeutic measure.

Further experiments by Ferry[3] indicated that the symptoms of meningococcus cerebro-spinal meningitis in laboratory animals are due in large part to the action on the central nervous system of a soluble specific toxin elaborated by the meningococcus, and that these symptoms can be modified or entirely prevented by the neutralisation of this toxin with a specific antitoxin. In a particular experiment, meningococcus toxin, when injected intracisternally into nine monkeys, produced symptoms similar to those found in meningitis following experimental inoculation of monkeys intraspinally with the live meningococcus. The symptoms of meningitis so produced by toxin may be greatly allayed or modified by mixing the toxin in proper proportion with its specific antitoxin before injection. A further point in favour of the direct relationship of this soluble toxin to the symptoms of meningitis—at least, in monkeys—is the fact that recovery from previous intracisternal injections of this toxin induced a state of active immunity against the killing dose of the live meningococcus inoculated intraspinally.

Ferry's work, if confirmed in all essential respects, would appear to provide a basis for: (1) the preparation of a polyvalent antitoxin of higher therapeutic potency than regular polyvalent antimeningococcus serum prepared from the same strains, and (2) the use of such antitoxin intravenously as well as intraspinally in order to neutralise the circulating and other toxin produced in the course of the disease. Serum has been used intravenously in cerebro-spinal fever in recent years both in America (e.g., by Carbonnell and Cook[5]) and in this country by Banks.[6]

A TRIAL OF THE METHODS

Since November, 1933, at the request of the Ministr of Health, a number of cases of cerebro-spinal feve have been treated with Ferry's meningococcus ant toxin in certain hospitals of the London Count Council. Owing to the low prevalence of the diseas in London during this period, the series so treated i far too small for satisfactory statistical analysis, bu it is felt that a preliminary statement from a clinica point of view may, at this stage, afford some guidanc to other workers in this field.

Cases of cerebro-spinal fever treated during th period at the Park Hospital, London, fall into tw groups:—

(A) Thirteen cases treated with Ferry's meningococcu antitoxin (M.A.T.). This was the treatment of choice, an was employed whenever a supply of antitoxin was availabl

(B) Eleven cases treated with a regular polyvalent anti meningococcus serum (A.M.S.) of British make. Thes were the cases which were admitted during various interval throughout the period when a supply of Ferry's antitoxi was not available.

Table I. summarises the essential information abou the two groups, omitting 3 cases fatal within 24 hour of admission. It will be seen that the two groups ar reasonably comparable as regards age-grouping, sex day of disease on admission, bacteriological type, anc method (routes, amounts, &c.) of specific treatment Group B shows a rather greater proportion admittec at a more advanced stage of the disease (i.e., beyonc the third day). On the other hand, 8 out of 12 cases in Group A were intensely acute or fulminating on admission, while in Group B only 4 out of 9 could be described in the same terms. The slight loading of Group B with "late" cases is thus perhaps compensated by the loading of Group A with more acute cases. Further, it appears reasonable to exclude from the deaths in Group A a case in which death on the eleventh day of treatment was shown to be due to cisternal hæmorrhage, the meninges being clear of exudate; and one from Group B in which the patient was almost moribund on admission and died within 48 hours. The net result of these exclusions is to yield

TABLE I.—*Summary of Cases and Results*

A = Meningococcus antitoxin. B = Antimeningococcus serum

‡ Excluding one death within 48 hours.

two reasonably comparable but very small groups, with the following mortality :—

Antitoxin series : 2 deaths from meningitis out of 12 cases.

Serum series : 4 deaths from meningitis out of 8 cases.

Although no conclusion can be drawn from such figures, there are several clinical considerations which strengthen the suggestion contained therein that the antitoxin may be somewhat more potent therapeutically than regular polyvalent serum, at least, for Group 1 infections. Thus, of the two deaths in the antitoxin series, one patient was admitted at the beginning of the investigation before the appropriate dosage of the antitoxin had been worked out. This patient received only four treatments, each consisting of 15 c.cm. intraspinally and 35 c.cm. intravenously, one on the day of admission, two on the following day, and one on the third day after admission, a total of 200 c.cm. Antitoxin treatment was then stopped, although the cerebro-spinal fluid was not clear. In the light of subsequent experience, it is believed that such dosage was inadequate. All subsequent cases received intensive dosage more or less conforming to the scheme shown in Table II.

TABLE II.—*Scheme of Intensive Serum Treatment*

The other death in the antitoxin series was a case of Type II. infection in a child two years of age. This case appeared to make no effective response whatever to the antitoxin applied as in the above scheme. It is the only one in the series of which this could be said, although the series included another case of Type II. infection in a lad of seventeen.

A striking clinical fact was the rapid recovery made by several desperately acute cases in the antitoxin series. Five of these patients had hæmorrhagic rashes. One was seen by an experienced observer just before admission, and the prognosis given was "probably about 12 hours to live." He recovered with the sequelæ of unilateral deltoid paresis and atrophy. One, with an illness of acute fulminating type, recovered quickly, but with the sequelæ of absolute (nerve) deafness, which appeared to be present from the time of admission. One, a hæmorrhagic case, recovered rapidly, but with the sequelæ of squint and nystagmus, which was present from a very early stage. It is not improbable that paresis present from an early stage, as in these cases, indicates a dangerous degree of meningeal involvement.

On the other hand, there are two factors which tend to offset the favourable results in this small series : (1) the absence of cases under the age of twelve months, which generally have a high rate of mortality ; and (2) the small proportion of bacteriological Type II. infections which generally show a poorer response to treatment than Types I. and III.

OTHER RESULTS IN LONDON

By the courtesy of Dr. E. L. Sturdee, of the Ministry of Health, I am able to refer to cases treated in other London hospitals by meningococcus antitoxin—viz., at the North Western Hospital, Hampstead, 6 cases with 2 deaths ; and at Brook Hospital, Woolwich, 7 cases with 3 deaths.

I am indebted to Dr. Alexander Joe, medical superintendent of the North Western Hospital, for details of his cases, from which it appears that both deaths were cases of Group 2 infection, one aged six months and the other aged twenty years. Three of the four recoveries were cases of Group 1 (Type I. or III.) infection, and in the fourth case the type was undetermined. The two fatal cases each came under treatment on the fifth day of the disease, and the recovered cases on 1st, 3rd, 3rd, and 5th days respectively. The ages of the recovered cases were 4, 13, 13, and 21 years respectively. In addition to the above, Dr. Joe treated two cases as controls during the period with a regular polyvalent meningococcus serum, the result being that one patient, aged thirty-five, treated from the second day of disease, recovered ; and the other, aged twenty-one, treated from fourth day of disease, died. It is of particular interest to note that all cases treated by Dr. Joe had intensive treatment—i.e., twice daily spinal serum during the early acute stage, and also intravenous serum in rather smaller dosage than that given at the Park Hospital.

I am indebted to Dr. J. V. Armstrong, medical superintendent of the Brook Hospital, for details of 7 cases. Six of these were cases of Group 1 infection, the type in the other being undetermined. The fatal cases were aged 2, 19, and 24 years, and were admitted on 2nd, 2nd, and 3rd day of disease respectively. All three were Group 1 infections. The four patients who recovered were one aged seven months and three young adults. The method of treatment at the Brook Hospital was less intensive than at the Park and North Western Hospitals, that is, on the more conventional lines of once daily spinal serum combined with intravenous serum.

To sum up, we have a record of 25 cases treated with meningococcus antitoxin in London, with 7 deaths from meningitis and 1 death from cisternal hæmorrhage, the meningitis having cleared up. Four of the patients were known to have Group 2 infections, and 3 of these died. The case-fatality rate in the series is just slightly better than the standard 30·9 per cent. death-rate given by Flexner[7] for his large and varied collection of serum-treated cases up to 1913. Clinical considerations, however, suggest that the antitoxin used in intensive dosage is particularly valuable in Group 1 infections.

Note on CISTERNAL AND VENTRICULAR PUNCTURE

One of our cases provided a valuable lesson on the danger of hæmorrhage from cisternal puncture in an irritable and struggling patient. The anæsthetic used up to this time was local, combined with morphine hypodermically, but this was insufficient to prevent a dangerous degree of movement while the needle was being inserted. As it happened, also, the needle used in the case was a lumbar puncture needle, gauge 16, which is the largest of the three sizes usually supplied. Considering the vascular nature of the membrane lining the cistern when acutely inflamed, it appears desirable to use the finest bore needle made for the purpose (viz., gauge 18). The needle should be sharp and be graduated in centimetres up to 5 cm. It is also desirable to use a general anæsthetic in the early acute stage. Although Evipan had been used in adults, the best results have been obtained with nitrous oxide gas and oxygen. The patient being quite still and the head flexed forwards as far as possible, the needle should be entered just above the spine of the axis, and gently pushed in an upward inclined direction *exactly in the middle line*, to pierce the occipito-atlantic ligament.

Cisternal injection of serum allows of a greater concentration of antibody in the basal cisterna, in the cerebral subarachnoid spaces, and in the ventricles around the choroid plexus[8] than is possible with lumbar injection. It also provides a valuable alternative site to the lumbar region when numerous injections have to be given. It is essential, however, that all precautions be taken to avoid hæmorrhage from the operation, as the consequences of hæmorrhage from the cistern may be much more dangerous than that from the theca.

The value of *early* ventricular puncture and injection of serum in infants has been stressed by Dopter, Lewcowicz,[9] and more recently by Cantacuzène,[10] who consider that the serum is thus brought into contact with the source of the infection in the cerebro-spinal system—i.e., the primary " chorio-épendymite." It appears to be reasonable to attempt this procedure in cases that are not responding to routine treatment at some time about the 5th–8th day of treatment, rather than to wait until blockage of the system has occurred. Our series included an instance of such successful interference. On the eighth day of treatment the temperature had not fallen and the cerebro-spinal fluid contained 1260 cells per c.mm. and meningococci. Double ventricular puncture, with removal of 16 c.cm. fluid and injection of 10 c.cm. serum, was followed in 48 hours by fall of temperature to normal and a clear fluid by lumbar puncture. Thereafter convalescence was rapid. The operation may be rapidly and painlessly performed in persons of any age, by the use of the modified Goetze channel borer described by Purves-Stewart.[11]

CONCLUSIONS

(1) Meningococcus antitoxin prepared by using, as antigens, soluble toxins of Types I., II., III., IV. meningococci, appears to be a potent therapeutic agent for Types I. and III. meningococcus meningitis, as shown in a recent small series in London. (2) Its potency in Type II. meningitis is much more doubtful. (3) It is suggested that intensive dosage—viz., twice daily spinal injections in the early acute stage, combined with one or more intravenous injections—is an important factor in the success of treatment.

ADDENDUM

Since this article was written, evidence has been obtained that the usual conditions of storage of meningococcal serum in hospital may be, in some cases, responsible for failure in treatment.

A batch of meningococcal antitoxin was received in June, 1934, and stored in the ice-chest of the dispensary of the hospital. Good results were obtained with this batch until February, 1935, when two cases, one of Type II. and one of Type I., in which recovery was confidently expected, failed to show any evidence of improvement, even with the ideal intensive courses of treatment. The agglutinating power of this batch on the Type I. strain isolated was then compared with that of a fresh batch of meningococcal antitoxin on the same strain. It was found that only *a trace of agglutination in 1 in 30 dilution and none in 1 in 60 dilution* occurred with the old batch, while the fresh batch agglutinated strongly in 1 in 30 and also less strongly in 1 in 60 dilutions. (The fresh batch has also been tested therapeutically and found to be rapidly effective.)

The ice-chest in the dispensary was next investigated. The routine practice was to put in fresh ice every 48 hours during the winter. The temperature inside the chest under these conditions in February was found to be between 51° F. and 54° F.—obviously a very unsatisfactory temperature in which to store serum for eight months. Cantacuzène (loc. cit.) has stated that meningococcal serum is a serum which ages very quickly, and ought not to be used more than 5 or 6 months after collection.

The makers of meningococcal antitoxin give an expiry date 18 months beyond the date of manufacture, and this is probably far too long for the serum to retain potency under the usual hospital conditions of storage. The point is especially important in the case of meningococcal serum, since in non-epidemic times there may be long intervals between admissions of cerebro-spinal fever cases to any particular hospital.

LARGE ENCHONDROMATA IN A CASE OF DYSCHONDROPLASIA

BY J. K. MONRO, M.D., M.Chir. Camb., F.R.C.S. Eng., M.R.C.P. Lond.

PROFESSOR OF SURGERY, KING EDWARD VII. COLLEGE OF MEDICINE, SINGAPORE; LATE SURGICAL FIRST ASSISTANT AND REGISTRAR, LONDON HOSPITAL

THE following case is thought worthy of record because of the good function that remained in spite of large enchondromata, and because of the association of dyschondroplasia with these.

A man of 23 was sent to the London Hospital on account of deformity of the hands. When he was three years of age, swellings in the fingers of both hands were first noticed and became progressively large, but he has always been able to dress himself and cut up his food. On leaving school at the age of fourteen he became a clay labourer. He managed the work well, but was eventually discharged by his employer, who feared some accident to the deformed hands. Since then he has worked for relatives or on his own account as farm labourer, cobbler, or going about on a bicycle as a pedlar. He has established his clientele, outside which he hesitates to go, for people are shocked when they see his hands (Figs. 1 and 2).

During the last year there has not been much change in the condition. There has never been any pain, and he can knock the hands without undue pain. He complains only of the disability and deformity due to the size of the lumps. When he was nine years of age the biggest lumps were removed at operation, 7 from the left hand and 9 from the right. The wounds healed well. Some of the lumps have recurred. Since he was eight there have been swellings on the toes of both feet. These swellings have grown larger, but do not seem to be changing now. They cause him no trouble, he wears ordinary shoes, and can play football. For as long as he can remember his left elbow has shown a projection. Occasionally it aches a little, and it is not as strong as the right elbow, while movements are not quite full.

At the age of three he fell off a stool and the left arm was bandaged for a week or two for a sprain. He has had no serious illness. There is no family history of abnormality of hands or feet. Father, mother, and five brothers and sisters are alive and well.

Examination.—He is undersized, 5 ft. 3½ in., but his brother is only 2 inches taller. On the left (Fig. 1) thumb, little finger, and carpus are perfect. The other fingers and their metacarpals show numerous cartilaginous tumours, hard rather than elastic, slightly translucent, the skin over the larger ones tightly stretched, shiny and showing prominent veins. These three fingers have sensation and mobility in their tips, but owing to enlargement of their proximal parts he is unable to use them and is willing to have them amputated. The radius is normal, but its head is dislocated from the humerus, beyond which it projects 1½ inches. The ulna shows at the middle of its shaft a subcutaneous prominence, at which the whole bone is angulated. The lower end is deformed and forms a movable joint with the radius, but does not reach within ½ inch of the carpus. There is an abnormal, rounded shadow to the radial side of the coronoid process, of which it is probably a fragment. Elbow movements are full, except for the last 5 degrees of flexion and extension.

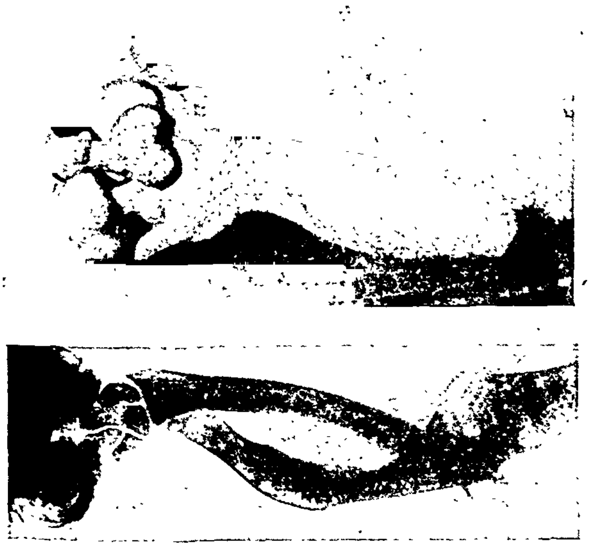

FIG. 1.—The left forearm and hand.

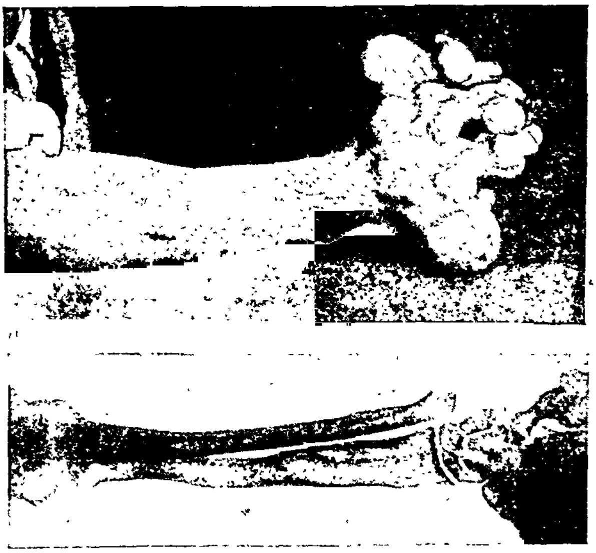

FIG 2.—The right forearm and hand.

In the right hand (Fig. 2) most of the phalanges and metacarpals show several chondromata, but all digits are useful, and he can write well. The nails of two fingers are displaced by tumours. Radiographs show that the carpus is perfect. The ulna is ½ inch longer than the radius, and its head is very prominent subcutaneously, while its styloid process is separate. The radius shows a widening of the lower end of its shaft, and here the bone is abnormally and irregularly translucent.

The feet show no disability, and he wishes no operative interference.

Treatment.—Mr. Robert Milne operated on the index and little fingers of the right hand and removed the largest two lumps by cutting and scraping. Care had to be exercised to avoid spontaneous fracture of the bones. Each tumour was covered with a bony capsule, but was easily cut with a knife elsewhere, the interior consisting of bluish cartilage. This was fairly vascular, was not encapsulated towards the rest of the bone, and showed no evidence of ossification. The wounds healed by the first intention, function was much improved, and the patient expressed himself as very well pleased with the result.

The way in which this man used such distorted hands was surprising. The fact that the tumours did not altogether cease growing at the age for union of epiphyses would suggest, according to Noble,[5] that they had become sarcomatous. The shiny appearance of some of them, with prominent overlying veins, seems to support this view, although the long history and the appearance on section do not. There was little doubt that ulceration of the stretched skin over the largest tumours would soon have occurred.

Ollier in 1899 described [1] as "dyschondroplasie" "an affection characterised by irregularity in development, evolution, and distribution of cartilaginous tissue in the bones in process of development, the cartilage seeming to be of normal structure and changing more or less slowly in the direction of ossification." His cases had pliable fingers, through the bones of which he could thrust a needle. Limbs were shortened, commonly on one side of the body only. Radiographs showed in the diaphyses streaks of diminished density resembling cartilage, and he was afraid that this cartilage might give rise to real tumours; but he did not report such an occurrence. He placed dyschondroplasia close to the condition of multiple exostoses ("diaphyseal aclasis"). The exostoses of this share with the cartilaginous masses of that the capacity for eventually undergoing ossification. He pointed out that these two conditions affect chiefly the period of growth, and that they may coexist. He contrasted dyschondroplasia with the condition of multiple chondromata. This arises also during the period of growth, but its neoplastic tumours remain indefinitely in a cartilaginous state, making no attempt at ossification.

Bentzon[3] compares the cartilage in dyschondroplasia with that in the callus in a healing fracture. He suggests that as cartilage is the body's material for repairing a fracture, so is it needed in dyschondroplasia to repair damage done by a hyperæmia resulting from imperfect sympathetic nerve-supply to the vessels.

The present case appears to be a link between the conditions which Ollier contrasted, for it shows large masses of typical enchondromata of hands and feet associated with dyschondroplasia of other bones. The haphazard distribution of ectopic cartilage in the diaphyses and the immunity of carpus and tarsus are characteristic of dyschondroplasia.[3] The appearance of long bones of only the forearms is shown in the accompanying illustrations, but similar abnormalities in his other long bones are now under investigation by the radiological department of the London Hospital.

It is interesting to find a short ulna on the left side associated with a short radius on the right, where the clinical appearance is that of Madelung's deformity. The deformity of the left forearm might, in view of the separation of a piece of the coronoid process of the ulna and the history of injury in infancy, be attributed to that common association[6]—a fracture of the ulnar shaft with dislocation of the radial head. The ulna, however, ends below in a "thimble-shaped mass of cancellous bone," and is typical of diaphyseal aclasis, in which condition inequality of growth between the bones of the forearm leads to a dislocation of the proximal end of the radius in a third of the reported cases.[2] Angular bends are not uncommon in dyschondroplasia.[4] In the present case the bowing of the ulna certainly accounts for its shortening, as much as does actual lack of length. The bowing could not have been due to yielding to thrust transmitted from the hand after dislocation of the radial head, for the lower end of the ulna does not reach to within half an inch of the carpus, while its joint with the radius is very movable. This deformity was therefore probably due not to trauma but to abnormality of bone growth.

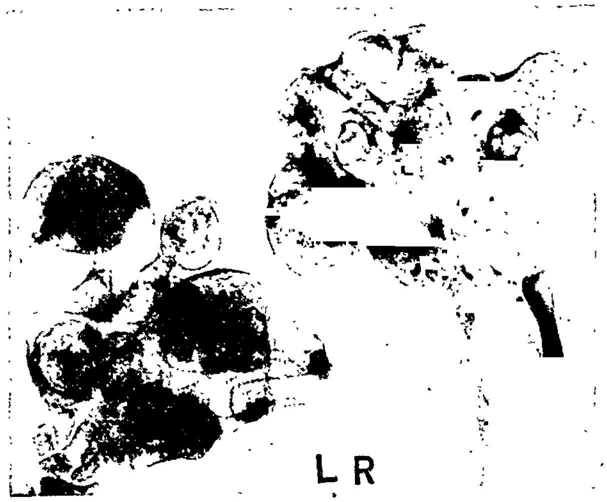

FIG. 3.—X ray of the hands.

My thanks are due for permission to publish this case to Mr. E. C. Lindsay, and for the radiographs to the radiological department of the London Hospital.

TRAUMA AND SARCOMA

BY J. J. M. SHAW, M.C., M.D., F.R.C.S. Edin., F.R.S.E.

ASSISTANT SURGEON TO THE ROYAL INFIRMARY, EDINBURGH; LECTURER IN SURGERY IN THE UNIVERSITY OF EDINBURGH

THE existence of a causal relationship between trauma and sarcoma of bone has long been a subject of dispute. A decisive opinion is difficult on clinical evidence alone and, unfortunately, it is not possible to find corroboration or refutation by the test of strictly comparable animal experiment. The frequent unreliability of the statements of patients and relatives in regard to the time, severity, and exact site of injury gives ground for an attitude of scepticism. This attitude is supported by the vast numbers of known injuries to bone in which malignant disease does not supervene. There is general agreement that "there may be something in it," but it is desirable to advance beyond this vague concession if such a step be justifiable. Apart from the medico-legal aspect, the subject is worthy of strict and continuous inquiry in the hope that new ground may be broken in the general field of cancer research if belief in the inter-relation of sarcoma and a single episode of trauma could be established.

Each addition to the sum of clinical evidence has some value.

A CASE RECORD

A. B., a clerk aged 21, was in apparently perfect health on a day in June, 1931, when he went for a swimming lesson in his luncheon hour. Misjudging his distance while swimming on his back, he struck the back of his head with moderate force against the tiled wall of the pool. The skin was not broken. He was slightly dazed and left the water on the advice of his instructor, but was able to dress and to return to his office at the usual time. A "bump" developed during the afternoon. In the evening he and his parents jested about the accident.

The swelling did not diminish in size as the days passed, and about a fortnight after the injury a friend who sat alongside him in the office remarked that it looked a little bigger than before. This agreed with the patient's own impression and led him to visit his doctor, who diagnosed a subpericranial hæmatoma on the occipital bone, and was of opinion that it would slowly disappear. The swelling, however, continued to increase very gradually and to become slightly tender. Seven weeks from the date of injury, *and in the absence of his own doctor on holiday*, he went to the surgical out-patient department of the Royal Infirmary, where he was seen by Mr. T. M. Millar, and 8 c.cm. of blood-stained fluid were aspirated from the centre of the swelling. An incision was advised for the complete evacuation of the mass but, at the request of the patient, this was delayed until his return from holiday a fortnight later. On the second occasion the surgeon was impressed by the increase in size and tenderness, and he removed a piece for diagnosis. The report of Dr. James Davidson, pathologist to the Royal Infirmary, dated Sept. 17th, 1931, was as follows: "The tissue examined is definitely malignant in character. There are undifferentiated malignant mesoblastic cells with an *irregular formation of a primitive type of cartilage and bone*. The growth is very vascular. The condition is that of an osteogenic type of sarcoma."

The patient was referred to Mr. Henry Wade, the surgeon-in-waiting, and admitted to hospital without delay. Radiography showed no bony change. At this time the swelling had reached a size of 8 × 6 cm., with a maximum depth of about 4 cm.; it was hard and tender. The biopsy incision had healed completely. The tumour was immovable upon the skull, and its central point lay very slightly to the left of the external occipital protuberance. One small soft gland was palpable in the left suboccipital region. There was no disorder of vision and the general health was good.

On Oct. 1st, *13 weeks from the date of injury*, a radical excision of the tumour mass with the overlying skin was carried out. Very slight pitting of the outer table of the skull was observed at the centre of the exposed area, and this was carefully chiselled over. Fourteen days later the whole surface was covered with granulation tissue. Forty milligrammes of radium were then applied on a moulded stent applicator at a distance of 1 cm. for 123 hours. After ten days at a convalescent home he was readmitted for irradiation of the suboccipital area. For this purpose 40 mg. of radium were applied for 192 hours in an applicator at 1·5 cm. At this time the wound still looked healthy and the small lymph gland, previously noted as enlarged from the debris of the hæmatoma, was not palpable.

He was discharged from hospital on Nov. 7th. Four weeks later he was readmitted with a recurrence of growth at one edge. This was the first of a rapid and inveterate series of recurrences against which further attempts at treatment proved unsuccessful. All further sections showed the same histological appearances as the first. Very soon evidences of pulmonary metastasis appeared, and the follow-up department intimated his death on March 28th, 1932, approximately nine months from the date of injury.

DISCUSSION

The sequence of events, precisely known, and the unusual site of the lesion seem to warrant the assumption that the sarcomatous process was initiated by the trauma in this case. The age of the patient within the period of body-growth, the moderate severity of the injury, the presence of a persisting hæmatoma with the absence of fracture or escape of blood on the skin surface—these are the outstanding points of resemblance in this case to the great majority of other recorded instances of similar tragedy. In such cases cells which are apparently normal in form and habit are converted into an abnormal type which is described as malignant because of its effect upon the host. Biologically one cell entity is not more malignant than another. The change in type is neither fortuitous nor lawless. Apart from the properties of growth and division which are common to all cells, environment is the determining factor in the modification of cell composition and morphology. It may be of some profit to discuss the rôle of the extravasated blood as a potent factor in environment. Its presence may influence profoundly the connective tissue cells around, and such cells will tend to breed true unless further environmental influences are sufficiently strong to alter their course.

The case quoted may be taken as a text in the description of a principle underlying the physiological process of repair which, under certain circumstances, may result in malignant disease.

In the repair of damaged tissues there are two processes which act harmoniously towards restoration of form and function in the great majority of instances. Firstly, the surviving cells in and around the area of injury are stimulated to proliferate so that an abundance of new raw material for rebuilding is made available in the form of granulation tissue. Secondly, these cells are acted upon by a complex group of factors which differentiate the raw material and effect an adjustment in them by which function is restored if the damage has not been too severe. Where repair is required, these two processes, the proliferative and the integrative, act in succession as related stages. This is well exemplified in a simple fracture of a long bone where the first stage consists of the appearance of a mass of new connective tissue cells in the area of the hæmatoma. Then, by the action of complex factors in the blood stream of the surrounding hyperæmic zone and the action of enzymes from the damaged bone-cells, the mass of young cells becomes changed into callus and further differentiation and adjustment takes place under local stresses and strains until, after several months, there may be found a complete restitution of the original form of the bone.

The stimulus to proliferation is given by substances derived from the extravasated blood and from the dead and dying cells of the other tissues. A similar effect of injury can be demonstrated in the vegetable world. Haberland and others have shown how substances diffused from the injured parts of turnip tubers and leaves induce proliferation in the healthy cells. It is unnecessary for present purposes to discuss the intimate nature and working of the stimulus, although a considerable amount of knowledge has been obtained upon the subject. It will be generally conceded that a stimulation is evoked in this way. This provision of fresh material forms the essential foundation for restoration.

The second stage of the differentiation of this raw material is, as yet, imperfectly understood. In addition to qualitative humoral influences from the rapidly re-established blood-supply, it is obvious that mechanical factors come into play, probably by influencing the distribution of the new capillary system. Where good anatomical replacement has not been attained after fracture, an entirely new system of buttressing may be produced, and this is obviously determined by functional requirements. To subserve the ends of function, the "free cells" (as we may regard the raw material) are acted upon by chemical and physical influences so that individual differentiation and group remodelling become apparent.

Two general statements may then be accepted. First, that healthy cells can be stimulated to proliferate in the presence of shed blood and of substances derived from the breaking down of other tissue cells. Secondly, that the differentiation of these young cells is due to superimposed factors related to the special function of the part. These superimposed factors affect not only the form and chemical composition of the cells, but also slow down their rate of division very markedly. It is of interest to note that the young cells of the proliferative stage of repair obtain their energy by the process of glycolysis in contrast to the oxygenation from the blood stream which characterises the differentiated cell. In this respect, the early undifferentiated cells of repair resemble those other types of "free cell," the morula stage of the ovum, growth on the tissue culture slide, and frankly cancerous growth.

The question now arises: "What will be the effect of the application of a stimulus to proliferation if it be not accompanied and intimately associated with the superimposed differentiating factors determined by functional loss, as in normal harmonious required repair? To illustrate the point, we may take a crude example. If an order be given by an authority whose word is law to a mechanic to supply and fit additional parts to an engine which is already in perfect running order, it is highly probable that his meddlesome interference will ruin the engine. Material may be brought in abundance to the builder's dump, but it will only cumber the ground until the master architect imposes a plan of construction upon the confused elements which have been assembled. Environment is law to the living cell. If the proliferative stimulus be applied, proliferation will ensue. If this is not regulated by all the inhibitions of differentiation, a disharmony will result. The unwanted stimulus becomes a goad.

The tar group will stimulate the proliferation of cells. In this work the constituent dibenzanthracenes play a prominent part. It will be remembered that dibenzanthracene has a close functional relationship to some other growth factors, such as auxin in plants and œstrin in mammals. Clinicians for many generations have employed the tars to accelerate the healing of broken surfaces such as ulcers, and there is general belief in their efficacy apart from their antiseptic properties. If, however, such a tar, adjuvant where healing is in process, be applied over a prolonged period to an intact area of skin where no repair is required, a slow and abnormal proliferative response is obtained. The cellular content of the epidermis increases and shows a heaping up in papillomatosis. Unlike the thickening of the epidermis as a protection against pressure and friction, the hyperplasia from the unwanted chemical stimulus subserves no function, and Kreyberg has shown that the blood-vessels, instead of expanding for service, will be, as it were, recalcitrant and evince a capillary thrombosis. Proliferation will nevertheless continue, and after the passage of many generations of cells it becomes their chief end, as with all free and "unemployed" cells. The metabolic demands of such cells are simple and easily met from the tissue fluids. Unless extirpated before they have spread from the original locus or destroyed by radiation, the way is open for the establishment of the undifferentiated group.

Another example may be given. The discharges of a raw surface, usually with a mild degree of infection, have a stimulating effect upon the cells which they bathe. This is the basis of the Winnett Orr treatment of the widely opened wound in osteomyelitis and is an accepted fact in clinical practice. The prolonged action of these stale discharges upon the epithelialised sinus or on the skin surrounding the cloacal opening from a badly drained cavity in osteomyelitis may initiate a proliferation which will culminate in carcinoma. The retention of stale discharges and secretions is a highly probable factor in the ætiology of carcinoma in many situations. An analysis of this subject has been made in a previous paper.

I submit that the action of a stimulus to proliferation where no repair is required may be noxious because under these circumstances there is an absence or gross insufficiency of the factors which induce differentiation. To revert to our text, the subperiosteal hæmatoma which lies in a cleft between a wall of intact bone and a dense and virtually intact periosteal membrane may persist for many weeks and is a well-recognised clinical entity. There may be no trace of functional impairment and a gross imbalance obtains between the proliferative and the differentiating aspects of the repair process. A true chronic irritant is in constant operation in the sense of the best definition of chronic irritation, namely, "the persistent manifestation of the process of repair." The multiplying cells lack a functional destiny.

It is unnecessary to emphasise the close similarity between such a conception of the initiation of this "conversion" type of cancer and that of the "continuing" or congenital type, of which the best example is the renal blastoma. In the conversion type, normal cells revert under a chemical stimulus to a primitive form which will persist in the absence of a subsequent adequate stimulus to differentiation. In the "continuing" type differentiation has failed to effect a change in all the cells which should come under its complex sway, and groups may continue to grow in what approximates to the free form of the morula stage. To Nicholson belongs the credit of providing an acute analysis of this failure in the congenital cancer group in which the Cohnheim "rest" theory finds its justification.

SUMMARY

A clinical case is recorded in which a known trauma appeared to be responsible for the development of sarcoma. The view is advanced that the prolonged action of a stimulus to proliferation, where function is unimpaired, may be responsible for the physiological aberration which is known as malignant disease.

CLINICAL AND LABORATORY NOTES

LATERAL SINUS THROMBOSIS DUE TO BACILLUS PROTEUS

BY A. B. PAVEY-SMITH, M.C., M.B., F.R.C.S.
AND
SINCLAIR MILLER, D.S.O., M.C., M.D., M.R.C.P.

THE patient was a nurse, aged 20, who reported sick at the Royal Bath Hospital, Harrogate, on Oct. 15th, 1934, complaining of pain in the lower jaw following the extraction of a tooth two days before. The temperature was 104° F. There were no other local symptoms. The tooth socket appeared to be clean, and there was no swelling of the alveolus or face.

The temperature continued high, with rigors on the 16th and 17th. The patient was seen by one of us (S. M.) on the 17th. There were then no localising signs and a blood culture taken at the time was sterile. On Oct. 19th a slight facial paresis on the left side developed. On Oct. 20th A.B. P.-S. was called in. The patient made no complaint of pain or discharge from the ear, and stated that she was not deaf, but had had ear trouble as a child. The right ear was normal: on the left side there was marked middle-ear deafness, granulations in the attic region, and a small amount of pus in the fundus; but no mastoid swelling or tenderness.

She was immediately transferred to the Harrogate General Hospital, where an operation was performed two hours later. Pus was found throughout a cellular mastoid; it was brownish and offensive. A large area of the lateral sinus lay exposed; the wall of this was discoloured but by no means necrotic. Its appearance suggested thrombosis. Exploration of the sigmoid portion with a hypodermic syringe showed the sinus to contain fluid pus. Culture from this grew *Bacillus proteus* only. A culture of the tooth socket proved sterile. The internal jugular vein was ligatured and divided above the common facial. The posterior part of the lateral sinus contained clot to within 1¼ in. of the middle line.

The fever continued, and after 48 hours both wounds, which had been partially closed, were reopened to ensure complete drainage and allow frequent irrigations with eusol. The exposure and drainage of the local infection appeared to have been adequate and complete; but the temperature, nevertheless, remained high, with repeated rigors, and it became evident that a general blood infection had become established. Neither blood transfusions nor antistreptococcal serum intravenously appeared to influence the course of the disease. Repeated examination of swabs from the operation wound gave *B. proteus*, and a further blood culture on Nov. 4th gave a pure growth of that organism. The clinical condition of the patient became progressively worse and she died on Nov. 6th.

It is rare that *B. proteus* is incriminated as the cause of a fatal septicæmia. Wilson [1] in the Medical Research Council's System of Bacteriology, quotes Maymone,[2] Warren and Lamb,[3] and Irimonoiu and Popa[4] as having reported cases in which it was the cause of septicæmia. In this case there can be little doubt that the patient had a latent *B. proteus* infection of the middle ear which suddenly became active, producing an acute generalised infection.

MENINGOCOCCAL MENINGITIS FOLLOWING FRACTURE OF THE SKULL

BY B. G. MAEGRAITH, M.B. Adel., D.Phil. Oxon.
BEIT MEMORIAL FELLOW

(From the Sir William Dunn School of Pathology, Oxford)

MENINGOCOCCAL meningitis is a rare complication of fracture of the skull, but in view of the high meningococcal carrier-rate sometimes recorded in England[1] the possibility of its occurrence should not be overlooked. The case here described was seen at the Royal Infirmary, Dundee, and I am indebted to Mr. F. R. Brown for permission to publish the clinical details, supplied by the resident medical officer.

Clinical history.—The patient, a soldier, was admitted to hospital on Sept. 16th, 1934, after a motor accident. There was a long cut in the median sagittal plane of the scalp, extending from the bridge of the nose well back over the frontal bone, in which there was an obvious depressed fracture. The wound edges were pared and sewn up on the day of admission and the patient was given an injection of antitetanic serum. He improved daily until Sept. 26th, when he complained of "stuffiness" of his nose and some discharge from it. On the 28th he complained of headache and ringing in his ears, but there was then no sign of meningitis and his temperature was not raised. Five hours later in the same day his temperature had risen to 102° F., and lumbar puncture was performed. The cerebro-spinal fluid obtained was cloudy, and on Oct. 1st the organism grown from it was shown to be a meningococcus. During the whole period Sept. 28th to Oct. 1st the patient became steadily worse. There was pronounced head retraction, almost of the gun-hammer type, and progressive cervical rigidity. The patient was extremely irritable and hyperæsthetic. On Oct. 1st he was transferred to the King's Cross Hospital, and died there.

Bacteriological diagnosis.—The organism isolated from the spinal fluid was sent to Oxford on Oct. 2nd. Smears showed Gram-negative cocci which were very irregular in size and staining reaction; there were many deeply stained giant cocci. The organism failed to grow from the first culture received, which was in the form of a stab inoculation into semi-solid agar. Further cultures were therefore sent from Dundee on semi-solid agar, serum agar, and Dorset's egg medium. The only one which survived the journey was the culture on egg medium, which has consistently proved to be the best medium for the transmission of living meningococci.

The organism grew rapidly in subculture on fresh egg medium and fermented both maltose and glucose. Standard suspensions of the killed organism in saline agglutinated at a serum dilution of 1 in 25 in Group I antimeningococcal agglutinating serum, and at a dilution of 1 in 1000 of a Group II. serum prepared from a Group II. organism grown from the nasopharynx of a carrier (Scott). On stab inoculation of the organism into 5 per cent. monovalent antimeningococcal immune serum agar,[2] haloes developed round the growth on the Group II. serum agar, but not on the Group I. serum agar. The organism was therefore diagnosed as a meningococcus belonging to Group II. and serologically similar to the Group II. organisms present in the nasal passages of carriers.

There is no evidence to show how the infection occurred in this case, but it seems probable that the patient was a carrier of Group II. meningococci, which entered his cranial cavity either directly through a fissure in the base of the skull, or through the blood stream. Unfortunately, no swabs of his nasopharynx were obtained.

Jakob[3] recently described a case similar to the above, in which meningococcal meningitis developed after a fracture of the skull and recovery took place after treatment with antimeningococcal serum. In this case the patient was a meningococcal carrier.

I wish to record my thanks to Prof. W. J. Tulloch for supplies of spinal fluid and cultures obtained from the above case.

CIRSOID ANEURYSM

BY C. F. SWINTON, Ch.M. St. And., F.R.C.S. Edin.
DEPUTY MEDICAL SUPERINTENDENT, HACKNEY HOSPITAL, LONDON

IT is rare to see a cirsoid aneurysm of any considerable size, probably because they are usually detected and treated early. This case may therefore be of interest to those who have not met with the condition.

A. B., aged 23, housewife, was admitted to Hackney Hospital on Sept. 25th, 1934, complaining of a swelling the size of a large walnut over the left mastoid region. She stated that she first noticed the swelling three years previously, when it was the size of a pea. It was said to have increased rapidly in size during the six months before her admission to hospital. Eight years ago she had been struck over the left ear with a cricket bat. No other history of trauma was forthcoming.

The patient said that she could not sleep when lying on her left side because of the "blowing noise in the swelling," and that as a result of sleeplessness she had been getting more and more irritable. On examination a pulsating mass of vessels the size of a large walnut could be felt over the left mastoid region. It extended in front of, above and behind the ear and downwards to about the tip of the mastoid. A well-marked thrill and bruit were present. The aneurysm involved the left posterior auricular vessel and appeared to extend to the temporal and occipital vessels. The question arose whether the intracranial vessels communicating with the aneurysm were likewise affected; but radiograms of the skull showed no increase in size of the grooves on the inner aspect of parietal and temporal bones. This finding was confirmed by injecting the aneurysm with lipiodol and immediate radiography of the skull.

Operation was performed on Oct. 6th under general anæsthetic. In view of the examination findings I was of the opinion that the left superficial temporal, post-auricular, and occipital vessels were involved, and in order to deal effectively with the condition, and also get a more bloodless operative field, it seemed advisable to do a primary ligation of superficial temporal and occipital vessels. These two vessels were exposed by the usual exposures in front of the ear and behind and parallel with the upper part of the posterior margin of the sternomastoid muscle respectively. The vessels were doubly ligated and divided between the ligatures.

A continuous interlocking catgut stitch of the scalp was inserted, extending in a semilunar fashion well up towards the vertex, from the site of exposure of the superficial temporal vessel to the site of exposure of the occipital vessels. A similarly shaped flap distal to the interlocking stitch was turned downwards, so exposing the aneurysmal mass lying on the mastoid area. The posterior auricular vessels connected with the vascular mass were caught up with forceps at their point of entry and under-run with catgut stitches. The excision of the aneurysmal mass was fairly easily and rapidly proceeded with, in what was practically a bloodless operation field. The scalp flap was then sutured back in position and the interlocking stitch removed. The wound healed by first intention and the patient made an uninterrupted recovery. She had no more trouble with noises over left side of the scalp, slept normally, and lost her irritability. She was discharged on Oct. 27th. She has reported several times since and appears perfectly well. She shows no sign of any return of her former trouble.

(1) There is a history of trauma—the time-honoured cause—although the swelling did not appear for five years afterwards; (2) the continuous interlocking stitch of the scalp after primary ligation of the superficial temporal and occipital vessels allowed one to work in an almost bloodless field, and so excise the aneurysmal mass with comparative ease.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF SURGERY

AT a meeting of this section held on April 3rd the chair was taken by Mr. PHILIP TURNER, the president, and Mr. R. L. HOLT opened a discussion on

Traumatic Shock

He described experiments on dogs and cats carried out by Mr. A. D. Macdonald and himself, and reviewed the evidence for the existence of traumatic toxæmia. Against the theory had been urged, chiefly by American workers, the following facts: (1) that no observer had satisfactorily demonstrated the presence of any depressor substance in the venous blood from a traumatised area; (2) that the difference in weight between normal and traumatised limbs found by Cannon and Bayliss failed to give a true picture of the extent of the extravasation and hæmorrhage into the damaged area; (3) that the circulatory changes of traumatic shock differed considerably from those produced by the injection of histamine or other depressor substances obtained from tissue extracts. The experimental work described had fully borne out these objections. In no experiment had there been any evidence of any depressor or histamine-like substance in blood withdrawn from a limb after trauma. If traumatic and histamine shock were compared, marked differences were seen. In traumatic shock there was diminished circulating blood volume, diminished output of the heart before there was any fall of blood pressure and marked pallor of the viscera and lungs; there was little bleeding on section of a solid viscus and very little blood in the heart, and the removal of quite a small quantity of blood caused death. In histamine shock there was no change in the blood volume, a fall in blood pressure preceded any diminution in the circulatory output, the viscera and lungs were congested, and the heart full of blood; solid viscera bled freely, and much more blood had to be removed before death ensued. Further experiments with dogs and cats had shown that on an average 45 to 47 per cent. of the total blood volume was lost by extravasation; thus the fall in blood pressure was accounted for by loss into the traumatised tissues.

The shock following muscle trauma came on so rapidly as to suggest that it was of neurogenic origin, but the fall in blood pressure took place also under spinal anæsthesia or after sympathectomy. Its cause was probably local vasodilatation. Experiments had shown no marked difference between trauma with and without spinal anæsthesia in cats. Nor did the induction of spinal anæsthesia benefit animals already in a state of shock. While there might be some neurogenic factor, its importance was very slight in comparison with the local loss of blood and plasma. This factor alone might sometimes cause death, but in other cases was only the initiating factor in secondary shock, which might be aggravated or maintained by many factors, such as idiosyncrasy and exposure to cold. It was easy to produce shock experimentally, but not so easy to maintain it. The healthy animal tended to recover: concentration of the blood was followed by dilution. Factors which maintained shock all stimulated the sympathetico-adrenal system, and intense or prolonged vasoconstriction had a very adverse effect.

Mr. Holt proposed to classify shock into three main groups: *hæmatogenic*, due to loss of blood volume; *neurogenic*, due to loss of central vascular tone—the shock of emotional states, and *vasogenic*, due to loss of peripheral tone—the shock of histamine and other drugs. Hæmatogenic or secondary shock was characterised by the following events, in order: diminished blood volume, a rise of the pulse-rate, vasoconstriction, a normal blood pressure, a diminished consumption of oxygen, and finally a serious fall in blood pressure. In primary or neurogenic shock, on the other hand, there was a fall of blood pressure with no rise of pulse-rate, vasodilatation, no diminution of blood volume or of oxygen consumption, while the fall in blood pressure was not serious if the respiratory centre was maintained.

The history of events in traumatic shock might then be expressed as follows: trauma produced diminished blood volume; this led to increased pulse-rate, vasoconstriction, diminished heart output, and a fall of blood pressure. If to the trauma were now added any cause of vasoconstriction, or any aggravating factor such as cold, vomiting, sweating, or pain, the blood volume was still further diminished, and this led to an increase of all the circulatory changes and a further fall in blood pressure. The result then was that the oxygen intake became less than the oxygen need, which resulted in a general increase in capillary permeability on the one hand and damage to the central nervous tissues on the other, the two factors together resulting in death.

Dr. DAVID SLOME described experiments carried out by Mr. L. F. O'Shaughnessy and himself, the trauma being produced by blows on the thigh muscles of the anæsthetised cat until the femur was broken. The theory which ascribed traumatic shock to a toxin elaborated in the traumatised tissues was based on the shock-like state produced by histamine. Trauma, after occlusion of the vessels, did not produce shock. Against the toxic theory were the following facts: (*a*) the quantity of depressor substances in the traumatised muscle was inadequate to cause shock; (*b*) occlusion of the venous return from a traumatised limb did not prevent shock; (*c*) there was no evidence for a toxic substance in the area of trauma or in the general circulation in the shocked state; (*d*) the changes observed in an animal in histamine poisoning differed from those seen in traumatic shock. On the whole, therefore, experimental evidence did not support the toxic theory. The theory of fluid loss had been set forth by Mr. Holt. There was no doubt that shock was due to hæmorrhage, but was it only hæmorrhage? Experimentally produced shock was not permanently relieved by blood transfusion, and the speaker and Mr. O'Shaughnessy had shown by various experiments that trauma to the limb of an animal supplied with blood by cross-circulation from a second animal, would produce shock in the first animal although only nervous pathways were intact. It was noticeable that if the fluid loss was only 14 to 20 per cent. of the total blood volume, as in some cases, the shock was none the less severe, and none the less rapidly fatal. There was no relationship between the blood loss and the survival time. The possibility of the lymphatic absorption of a toxin must not be forgotten when emphasising the results of occlusion of the blood-vessels. The nervous factor had been studied by administering trauma under spinal anæsthesia, which was undoubtedly beneficial to the animal, and by complete denervation of the limb before trauma. Both these measures modified the onset of shock, and a discharge of nerve impulses from the traumatised area had been demonstrated experimentally. Their findings, therefore, suggested that the nervous factor was important and reinforced the effect of fluid loss.

Sir HENRY DALE, F.R.S., reviewed the circumstances in which the idea of traumatic shock had come into prominence. Early in the war secondary wound shock had been causing much anxiety, and a committee had been appointed to investigate the condition. At that time the two rival conceptions had been exhaustion of the vasomotor centre with general relaxation of the arterioles, and over-activity of the vasomotor centre with lack of blood in effective currency. Hæmorrhage or sepsis could obviously produce the latter condition, and both were present in most of the war cases. It was not surprising that work under peace conditions had failed to substantiate the earlier conclusions. Neither extravasation nor painful nerve impulses were adequate explanations of shock. What did the sensory impulses do? Arterial dilatation, however produced, caused fall in blood pressure but not oligæmia—rather it increased blood volume, because fluid was taken up from the tissues. Yet in traumatic shock there was oligæmia, as in histamine shock. Nevertheless, histamine could certainly not be the cause of traumatic shock, because of the rapidity of its action. The possibility of absorbed substances, with a long-range action, had not been ruled out, however, as an important factor in some kinds of shock.

Mr. L. F. O'SHAUGHNESSY said that although the failure of Holt and Macdonald to confirm the experiments of Dr. Slome and himself was at first sight disappointing, yet the traumatised limb with a broken femur was a different proposition from one in which the muscle only was injured. In one respect Mr. Holt did grave disservice to the solution of the problem. The term "secondary shock" was a mistaken one: originally used to explain death a long time after an injury, it had lain dormant until the great war, reappearing at about the same time as the theory of traumatic toxæmia. He had never seen a case of secondary shock in clinical practice, nor met a satisfactory account of it, nor had he seen a case experimentally produced. Apparent initial recovery followed later by shock had always been explainable in the war by hæmorrhage, gas gangrene infection, or some other factor. Whereas recovery from neurogenic shock was immediate, recovery from the mildest degree of surgical shock took two or three hours. Clinical experience showed that nociceptive impulses might exist without pain.

Prof. R. J. S. MACDOWALL reminded surgeons that it would be a pity to assume that the information in the ordinary text-book on the control of the circulation represented the sum total of present knowledge. It was not generally known that adrenaline contracted the intestinal vessels and was a profound dilator of the muscle vessels. Experimental physiologists came across curious manifestations of surgical shock. He had seen shock result in an animal from stimulation of the depressor nerve. This phenomenon was not explicable on any ordinary basis and might be due to the production of vasodilator substances in quantities too large for the body to deal with in the peculiar circumstances.

Dr. GALE spoke of experiments at St. Bartholomew's Hospital showing the relation between the site of a surgical operation and the rise in blood-sugar. This rise seemed to be greater the more the solar plexus was affected by manipulation.

Mr. C. HOPE CARLTON recalled observations on 50 children in Canada who had been treated for a condition indistinguishable from secondary shock by an exsanguinating transfusion. The condition was hardly improved at all and could therefore not well have been due to the presence of toxins.

The PRESIDENT said that surgeons in the war had been much impressed by cases of secondary shock, usually associated with hæmorrhage. The typical case had closely resembled the experimental conditions described by the openers. A soldier suffering from severe crushing, laceration, and fracture would appear to be progressing well, and then a small hæmorrhage would produce a profound and fatal degree of shock. The condition had been prevented by early treatment and gas-and-oxygen anæsthesia.

OPHTHALMOLOGICAL CONGRESS

THE fifty-fourth annual congress of the Ophthalmological Society of the United Kingdom was held at the Royal Society of Medicine on April 4th, 5th and 6th, under the presidency of Mr. R. Foster Moore. The occasion was of more than usual interest in that it coincided with the meetings in London of the International Ophthalmic Council, the International Association for the Prevention of Blindness, and the International Organisation against Trachoma. A large number of foreign guests were therefore present and the proceedings had an international tinge.

The meetings of the visiting associations were mainly concerned with two points of view, both of social and legislative as well as scientific interest, namely, that of prophylaxis and that of adequate statistical recording. Under the first heading were discussed such subjects as the ætiology of trachoma, the various hereditary conditions of the eye leading to blindness and their social consequences, the prophylaxis of ophthalmia neonatorum, and so forth. Under the second, papers were read on the classification of the causes of blindness and suggestions made for the collecting of accurate and full statistics relating to the blind population in the various countries taking part. Prof. Emil de Grosz (Buda-Pesth), Prof. van Duyse (Ghent), Prof. A. Franceschetti (Geneva), Prof. von Szily (Münster), and Mr. A. F. MacCallan (London) contributed notable papers, and the general atmosphere was one of coöperative and hopeful planning for the future.

At the meeting of the British society the president, Mr. Foster Moore, read an advanced and inspiring paper on the uses of radium in intra-ocular lesions. Mr. Foster Moore is an acknowledged pioneer in this field, and his results are distinctly hopeful. The types of growth for which this somewhat heroic treatment is indicated are among the most malignant known, namely, glioma retinæ and melanotic sarcoma of the choroid. (Angiomatosis retinæ, dangerous to sight though not to life, has also given encouraging results.) The president did not advocate the substitution of radium therapy for the proven treatment by excision except in cases where the only eye was involved or where excision was refused. Glioma of the second eye was, he said, a distressing condition for which radium offered the only hope apart from excision. He cited a successful case of five years' standing with no recurrence or dissemination. The application was made by means of a radon seed, usually of 1 millicurie, filtered through 0·5 mm. of platinum, either introduced directly into the growth through an incision in the sclera or sutured to this latter over the situation of the growth and left in position for four days. Accurate localisation and delicacy of technique are essential and the operation is not without risk, since the optimum needed to kill the growth cells is very near the exposure which will start degenerative changes in the lens and normal retina. The address was certainly an outstanding contribution to the subject of radium therapy.

The president's address was followed by a discussion on diseases of the blood and their ophthalmological complications, opened by an ophthalmic surgeon (Sir Arnold Lawson), a physician (Dr. Letheby Tidy), a biochemist (Prof. E. C. Dodds), and a hæmatologist (Dr. P. N. Panton). The relationship of retinal hæmorrhages and exudates to the blood count, coagulation time, calcium content, and other blood changes was discussed from the various points of view. The afternoon was devoted to contributions by the guests, notably a paper on the localisation of retinal holes in detachment, by Dr. Marc Amsler (Lausanne), and on the treatment of the condition by a modified diathermy current by Dr. Leon Coppez (Belgium).

The following sessions were occupied by a variety of papers of interest. Mr. Tudor Thomas gave a detailed account of the microscopic appearances of two successful corneal grafts in man, the first available record on the subject. Mr. Cardell read a suggestive paper on the possible uses of polarised light in ophthalmoscopy and retinoscopy. By incorporating a double Nichol prism in the ophthalmoscope it was possible to abolish the corneal reflex and so to examine the macula easily through the undilated pupil, a procedure often of great value. Miss Ida Mann read a paper on an embryological theory of oxycephaly, which indicated that the possible primary aberration of growth lay in the visceral mesoderm of the maxillary process.

REVIEWS AND NOTICES OF BOOKS

Recent Advances in Sex and Reproductive Physiology

By J. M. ROBSON, M.D., B.Sc., F.R.S.E., Beit Memorial Fellow, Institute of Animal Genetics, University of Edinburgh. London: J. and A. Churchill Ltd. 1934. Pp. 249. 12*s.* 6*d.*

THERE are probably few physiological problems which have been subjected to more active investigation in the last ten years than that of reproduction. As the literature gains in volume and the terminology grows in complexity, so does the need arise for a periodical survey by an authority who, while familiar with intricacies, can yet direct our attention to its salient and well-established facts. In a preface, Dr. Robson explains that his treatment has been selective. He has been compelled to discuss very briefly, or even to dismiss altogether, much data which appear to have no permanent bearing on the problems which, for him, are important. Such a handling of the subject is clearly necessary, but equally clearly it will evoke criticisms from those whose work has been cursorily dealt with or overlooked. Making allowances for this and for the fact that it is probably now impossible to write a book on reproductive physiology which will please everybody, Dr. Robson's work may be regarded as fulfilling its primary purpose.

The book falls naturally into two parts. In the first, consisting of five chapters, are described the nature of the sex cycle in different animals, cyclical alterations in uterine endometrium and muscle, and the functions of œstrin and lutein. This part thus furnishes an anatomical and physiological introduction to the complex processes described in the six later chapters. These deal with the relation of the pituitary gland to ovarian activities, ovulation and fertility in primates, hormone production and excretion, pregnancy and parturition, and the mammary functions. The book concludes with a chapter on clinical applications which will be of special interest to those "clinicians who seek to incorporate into their practice recent advances in science," for whom, Prof. F. A. E. Crew explains in an introduction, this book has been primarily written. Clinical applications of our present knowledge are (1) diagnostic, (2) therapeutic. "In the field of diagnosis," says the author, "important and even spectacular progress has been made, whereas the therapeutic application of hormones yielded apparently meagre and disappointing results." The diagnostic functions are clearly described: the Aschheim-Zondek test in its various applications, the Friedman test, and the Brouha test. Indeed, details of technique are included which would be of interest to the laboratory worker rather than to the clinician. The therapeutic applications are less clearly set forth. It is suggested that œstrin may have therapeutic uses in curing amenorrhœa and sterility, in terminating pregnancy, in relieving symptoms of the menopause, and in treating hæmophilia. The therapeutic use of corpus luteum hormones is, we are told, not yet feasible. The gonadotropic hormones of the pituitary have been administered for amenorrhœa, spasmodic dysmenorrhœa, the prevention of abortion, ovarian bleeding, and for certain pelvic inflammatory conditions. Though definite instructions as to the therapeutic uses of these hormones are as yet impossible, the clinician might have been grateful for clearer guidance as to their possibilities. The book is somewhat indifferently illustrated with diagrams, photographs, and microphotographs which are not always very clear or well explained. In parts it is carelessly written. Thus the textual description on page 9 does not correspond to the diagram on the opposite page and there are several examples of loose phrasing (such as the use of the word "menstruation" for the term "menstrual cycle" on pages 94 and 95) which have confusing effects. On the whole, however, the medical reader is deftly guided into and through the obscurities of a difficult subject.

Biochemistry of the Eye

By ARLINGTON C. KRAUSE, M.A., Ph.D., M.D., F.A.I.C., Instructor in Ophthalmology, the Johns Hopkins Medical School. Baltimore: Johns Hopkins Press; London: Humphrey Milford, Oxford University Press. 1934. Pp. 264. 15*s.*

IN this monograph, No. 2 of the series issued by the Johns Hopkins Hospital and University, Dr. Krause has attempted to review briefly the investigations which have been carried out on the chemistry of the eye. The work is divided into eight chapters, which deal in order with the chemistry of the external secretion and conjunctiva, the sclera, the cornea, the uveal tract, the retina, the aqueous humour, the vitreous humour, and the lens. A very full bibliography is given at the end of each chapter, and the various conclusions reached by different workers are summarised and critically discussed. Forty-nine pages throughout the book are devoted to a study of the chemistry of the lens, and this forms the largest chapter in the work. We would have liked to hear more of the author's views on the theories of the formation of the aqueous humour, and it seems a pity that the soft, low-tension eye of diabetic coma receives no mention.

The monograph will doubtless prove of great value as a work of reference both to ophthalmologists and biochemists; some ophthalmologists who consult it may be dismayed to find that Dr. Krause presupposes a knowledge of general biochemistry and its related subjects in his readers. It would, however, have been impossible to keep the book within reasonable compass if this assumption had not been made, and for those who possess the equipment to appreciate it this work provides a valuable addition to the literature of the chemical side of ophthalmology.

Psychology and Health

By H. BANISTER, M.Sc., Ph.D., Director of Psychological Studies, St. John's College, Cambridge; Lecturer in Experimental Psychology in the University. London: Cambridge University Press. 1935. Pp. 256. 7*s*. 6*d*.

THIS is a very fair exposition of modern psychological medical problems by a trained psychologist who is a practising psychotherapist to the Papworth Village Settlement. Dr. Banister is not only experienced in the psychopathic problems of children and adults, but his training is catholic and methodical, and his comments demand respectful understanding. After a preliminary chapter on psychology and the physician, in which he urges the general practitioner to equip himself to undertake some measure of psychological treatment, at least of the child, Dr. Banister proceeds to a useful consideration of the senses in which he intends to use some of the common psychological terms, whose meaning in any article tends to vary with the author's school of thought. Successive chapters deal with mental defect; the problem child; infantile sexuality; further development; the annoyances and troubles of the healthy; effects of ill-health; the invalid; suggestion; hypnosis; the unconscious and dissociation; conversion hysteria; anxiety states; and compulsion and obsession. Thereafter the outstanding theories of Freud, Jung, Adler, and Janet are discussed each to a critical exposition, and the final chapters are concerned with methods of treatment.

Dr. Banister raises an interesting distinction between dissociation, according to Janet, and conversion hysteria, according to Freud. His account of child problems is sound and unprovocative, inclining to environmental interpretations rather than to the anxiety theories of the Freudians, which account for child neurosis on the basis of instinct frustration, particularly of infantile sexuality. This knotty problem, which forms the basis of psycho-analytic play technique, is made the subject of a special chapter. Dr. Banister rejects the psycho-analytic insistence on infantile sexuality, and suggests alternative interpretations which will appeal to all but strict Freudians. According to him, curiosity rather than actual sexual desire is the keynote of the child's interest in procreation and physical functions.

Dr. Banister is by no means an opponent of Freud; his work shows him to be a critical adherent of the wider principles. The zealots will hold that his doubts about infantile sexuality puts him definitely outside the pale; whereas those to whom not only psychoanalysis but any of its derivatives are anathema will find him far too sympathetic to the many variants of modern theory and practice, which he discusses with obvious understanding. It seems likely that his work will appeal to those for whom he writes—medical students and practitioners who need to understand something of the working of the human mind in order "to direct to favourable ends the psychological processes which inevitably influence the course of every life."

Physiology in Modern Medicine

Seventh edition. By J. J. R. MACLEOD, M.B., LL.D., D.Sc., F.R.C.P., F.R.S., Regius Professor of Physiology in the University of Aberdeen. Assisted by PHILIP BARD, Professor of Physiology, Johns Hopkins University School of Medicine; EDWARD P. CARTER, Adjunct Professor of Medicine, Johns Hopkins University; J. M. D. OLMSTED, Professor of Physiology, University of California; J. M. PETERSON, Lecturer in Experimental Physiology, University of Aberdeen; and N. B. TAYLOR, Professor of Physiology, University of Toronto. London: Henry Kimpton. 1935. Pp. 1154. 36*s*.

Prof. J. J. R. Macleod, whose death we had to record a few weeks ago, set his hand 17 years ago to the task of helping to bridge the gap between physiology and medicine. He was distressed, as so many others have been, at the contrast between the scientific and experimental atmosphere of the laboratory and the empiricism that dominates a great deal of clinical medicine; so he offered to the clinicians his now well-known book on "Physiology and Biochemistry in Modern Medicine." The book was intended to provide a basis of physiology out of which the inquiring clinician might begin to construct his own functional pathology. It was to deal with those parts of its subject whose bearing on medicine is closest, and to treat them as far as possible from the human, as distinct from the general mammalian, standpoint. The book has been of great value. In this last revision the collaborators have been increased to five—four physiologists and one physician; many chapters have been rewritten, and much new and useful material has been incorporated.

This is not to say that the gap which led to the original production of the book has yet been successfully bridged. The clinical end of the bridge is not so firmly grounded as the physiological end. The authors sometimes seem to have overlooked the very point at which the physician is unable to make progress. For example, a physiologist's critique of the various forms of test-meal would have been welcome; the statement that gastric HCl is "decreased" in pernicious anæmia, and the assertion that dystrophia adiposo-genitalis is undoubtedly due to a lesion involving the anterior pituitary, suggest a lack of familiarity with ascertained clinical and pathological fact. Even in his own field of carbohydrate metabolism Prof. Macleod has omitted to discuss the mysterious effect of the composition of the diet, on the efficiency with which the body deals with ingested sugar, an effect which has been known for years, and which no doubt underlies the success of the modern high carbohydrate diabetic diet.

Perhaps it is too much to expect the interdigitation of physiologist and physician over the whole range of medicine, and both may be better served by collaboration in restricted fields.

Synopsis of Pediatrics

By JOHN ZAHORSKY, A.B., M.D., F.A.C.P., Professor of Pediatrics and Director of the Department of Pediatrics, St. Louis University Medical School. Assisted by T. S. ZAHORSKY, B.S., M.D., Assistant in Pediatrics, St. Louis University Medical School. London: Henry Kimpton. 1935. Pp. 359. 17*s.* 6*d.*

THE word "*synopsis*" has come to have such a specialised connotation in this country that it usually suggests a cram-book on the lines of the old "Paley's Ghost" of the Little-go. This volume is not that sort of synopsis, but is, rather, a short text-book of pædiatrics; it is well illustrated with 77 photographs and diagrams and 6 coloured plates, and should serve as a useful introduction to the subject as well as a manual for rapid revision. It has been reduced to its very modest size by the use of type that is unpleasantly small for prolonged study, but it contains a vast amount of material at a most reasonable price. It is marred by a few definite misstatements and omissions which could easily have been avoided. Gaucher's disease, for instance, is described as "a chronic enlargement of the spleen caused by a deposit of large endothelial cells." Banti's disease, twice referred to, is said to be extremely rare in childhood, but is not described or defined. It is a pity that radiograms of the chest have not been consistently reproduced as either positives or negatives. These defects, however, are not serious enough to make the book unsuitable for its purpose, and students who want a concise review of pædiatrics, without entering deeply into controversial matters, will be well advised to procure it.

Groedel's *Roentgendiagnostik in der Inneren Medizin*

Lief. 1. Fifth edition. Edited by HEINZ LOSSEN. Munich: J. F. Lehmann. 1934. Pp. 186. RM.24.

THIS book forms the first part of the fifth edition of Dr. F. M. Groedel's text-book and atlas of X ray diagnosis, which is being produced in six parts by many authors. Groedel and H. Lossen contribute a very full description of technique, including that of kymography and cinematography. The same authors discuss the legal aspects of radiology, while Groedel and K. Saller deal with physical constitution. From the pen of the late Prof. G. Holzknecht comes a description of his technique for the localisation and measurement of internal organs. O. Schnaudigel provides a short chapter on the eye.

To the general radiologist the most interesting chapter is that by H. Wintz on the changes found in disturbances of the internal secretions. It is a mine of information on a little-known subject. H. Peiper's account of the investigation of the nervous system is invaluable to those radiologists who have opportunities of carrying out such work. We note the author's admonition that encephalography and ventriculography are not to be undertaken lightheartedly by the inexperienced.

A word must be said about the format of this work. Its 41 plates are among the best we have seen. The letterpress is rendered clear by the skilful use of different types. It is a puzzling fact that only in Germany do text-books on radiology seem to be produced in the grand manner. There is evidently a market for them such as does not exist in countries which consider themselves more prosperous. The editor, authors, and publishers alike are to be congratulated on their work.

British Journal of Children's Diseases

IN the January–March issue (Vol. XXXIII.), in a paper entitled Some Observations on Rheumatism in Childhood, Dr. T. Warwick Preston reviews the work of the past four years at the Elizabeth Bullock, Putney, and Downham Supervisory Centres, his conclusions being as follows: (1) pains of the "growing pain" type occasionally prove to be an insidious form of rheumatism which may attack the heart; (2) many pains which may appear to be rheumatic are caused by minor orthopædic conditions and general debility; (3) a certain number of children continue to complain for a prolonged period of aching limbs for which no adequate explanation is forthcoming; (4) cases of insidious carditis are usually the result of a definite subacute attack of rheumatism; (5) "growing pains" are uncommon in children definitely known to have had acute rheumatism; (6) among children with serious rheumatic carditis the general condition is remarkably good and complaints of all kinds are rare; (7) there is evidence that the heredity factor is a real one.—In continuation of his Analysis of Over Four Thousand Cases of Educational Deafness, Mr. Macleod Yearsley deals with cases of acquired deafness due to congenital syphilis and chronic middle suppuration (for which in the great majority of cases no cause could be found), chronic middle-ear catarrh, otosclerosis, and injuries of the ear.—Dr. P. H. Newman reports a Case of Double Riga's Disease in a male infant of 6 months, in whom an ulcer first appeared on the frenulum and under surface of the tongue and four months later on the dorsum. The condition healed rapidly on each occasion after removal of the incisor teeth.—Dr. V. Kolew of Satanow, U.S.S.R., reports a case of Premature Greyness of the Hair in a girl aged 12, whose hair had begun to grow grey on both temples two years previously, since when canities had spread all over the head with the exception of the eyebrows and eyelashes. The child was otherwise normal, and there were no similar cases in the family. Kolew attributes the condition to the fact that both the parents were elderly at the time of the child's conception.—The abstracts from current literature are devoted to tuberculosis.

NEW INVENTIONS

A NEW LOBECTOMY CLAMP

THE clamp here illustrated has been designed by us for holding and crushing the bronchus and pedicle of the lobe during the operation of lobectomy. The ordinary snare occasionally comes off the pedicle at the critical moment, but this clamp will give a firm hold and not slip, as it has great crushing power, while the longitudinal serrations of the blades render it possible to cut the lobe away absolutely flush with the clamp with safety. The upturned end renders the tying of ligatures or stitches round the pedicle easy. The clamp is made in two sizes for adults or children, and is now manufactured by the Medical Supply Association Ltd., 167, Gray's Inn-road, London, W.C.1, and is available for general medical supply.

LONDON: SATURDAY, APRIL 13, 1935

SCOTTISH SICKNESS EXPERIENCE

WHAT death-rates meant to the health authorities last century, sickness-rates mean to-day. The sanitary movement last century demanded for its efficiency registration of deaths and, later, notification of infectious diseases. The health movement this century, as it develops more and more into individual care, is creating a similar demand for exact information on the incidence and distribution of all forms of sickness. This demand may never be met by any complete system of sickness registration—probably it would be undesirable if it were; and it is therefore necessary to turn to full account every available channel of information. The hospitals, schools, and insurance medical practice are the most obvious sources of exact data; and of these, by far the most valuable, both for medicine generally and the work of the health authorities, is the last. Four years ago Scotland initiated a scheme for the recording, analysis, and study of sickness among the insured population. The idea was to extract from insurance medical certificates information about the causes of incapacitating sickness, and its distribution by age, sex, locality, and occupation. The motives behind the scheme were no doubt mixed: the Department of Health, who are responsible for it, could not be blind to its uses for checking up on certification. But from the first the Department, as well as outside observers, saw that it would justify itself only by the light it might throw on medical and public health problems. The scheme has obvious limitations. For example it records only incapacitating sickness; and it deals only with the industrial population between 16 and 65 years of age (more than a third, however, of the total population of Scotland). But with all these and other limitations the scheme is the biggest attempt yet made in Great Britain to supplement the national system of vital statistics. It should give us a measure of the extent of incapacitating sickness in this large part of the population, should reveal the causes in their order of importance, variations by age, sex, locality, and occupation, and should reach out to tell us why.

The fourth report on the scheme, that for the year to June 30th, 1934, has now been published.[1] It contains, in addition to all the features of the previous reports, special studies on sickness in certain occupational groups (mining and agriculture and fishing), the increase in infectious diseases, and sickness in the Highlands and Islands. It is the best of the series, and should finally remove any doubts that may have been entertained about the value of the scheme. In some respects the sickness returns for the year are the most favourable since the summaries were first compiled four years ago. The insured population numbered 1,689,468, and the total number of completed incapacities was 341,066 (a rate of 202 per 1000 insured persons) compared with 401,744 (238 per 1000) in 1932–33, 359,811 (213 per 1000) in 1931–32, and 378,742 (224 per 1000) in 1930–31. Married women show by far the highest rates in each of the four years, but these are coming down faster than the rates for single women and for males. The days of incapacity amounted to 16,870,515, equivalent roughly to 10 days of sickness per insured person during the year, a figure that is appreciably lower than that for last year and slightly lower than the average (10·28 days) for the preceding three years. The improvement over the previous year is mainly due to a big reduction in cases of influenza and, in a lesser degree, its correlatives—bronchitis and pneumonia. There were increases in infectious diseases (chiefly scarlet fever, erysipelas, and diphtheria), minor diseases of the upper respiratory tract, tonsillitis, skin diseases, superficial septic and inflammatory conditions, rheumatism, accidents, and nervous debility, and slighter increases in tuberculosis and cancer. Sex and age differences in the incidence and duration of incapacities are set out in a series of tables but, apart from the rapid improvement in married women, there is no outstanding new point to record. The geographical distribution shows, as last year, a lower incidence and higher duration in burghs than in counties. The detailed analysis brings out that the incidence-rates in mining areas are conspicuously high, and in the highland rural districts conspicuously low. Among nine broad groups of occupations, mining shows by far the highest sickness-rates for males (326 per 1000). It is followed by textile and paper workers (208), makers of foods and drinks (194), transport workers (192), agriculture (165), metal trades (164), commercial occupations (160), building trades (156), and personal service (138).

The special study on sickness among miners during the three years ended June 30th, 1933, is expressly a preliminary effort to introduce the subject of occupational sickness. The difficulties are pointed out. Selective recruitment, for example, the concentration of particular industries in a few localities and other factors have to be allowed for. But the difficulties will not seriously impede a study that is of major importance to preventive medicine. Hitherto knowledge of occupational sickness has depended mainly on death-rates. As previous reports in this series have pointed out, there are gross differences between causes of death and of incapacitating sickness, and a large proportion of the total incapacities are not such as to terminate fatally. Preventive measures therefore may easily miss the mark if they are based only on a study of death-rates. It is brought out in this special study that, over the three years, miners have an average annual incapacity of 18 days per miner, compared with 8·7 days for other men. Men in the coal-fields not being miners have a lower average duration of incapacity not only than miners but than all males in Scotland (less miners)—a fact which

---

[1] Department of Health for Scotland. Report on Incapacitating Sickness in the Insured Population of Scotland during the year July 1st, 1933, to June 30th, 1934. Edinburgh: H.M. Stationery Office. Pp. 72. 9d.

and the medical profession. The opposition seems to be coming from those who, like Lord SANDERSON, wish to see all medical services municipalised or nationalised, and who look forward to the time when all sickness will be a charge on the State.

A number of reasons have contributed to the popular demand for increased pay-bed accommodation. Illness is less readily tolerated and health more anxiously sought than it was a generation or more ago. There is certainly less fatalism with regard to ill-health, attributable, we may hope, to the wider public realisation of what medicine has now to offer in the alleviation and cure of sickness. It is common knowledge, for instance, that acute appendicitis can be cured by operation, and that a failure to recognise it may be fatal; that under optimum conditions a broken bone can generally be set so that good functional recovery results; that dyspepsia, even of long standing, may be due to an ascertainable cause whose removal leads to permanent relief. But it is also true that for the diagnosis of acute appendicitis a specialist opinion may on occasion be required, and for its surgical treatment a competent surgeon, an operating theatre, an anæsthetist, and skilled assistance; that an X ray plant may be necessary not only for the diagnosis of a fracture but also for periodic control of its progress under treatment in plaster or splint; and that for the treatment of dyspepsia not only radiological examination of the teeth and of the whole digestive tract may be needed, but pathological investigation of the contents of the stomach and of the excreta, as well as of the blood, together with continued observation of the patient—all this in what may seem at first to be a simple case. Reckoned in terms of money the thorough investigation of a case of serious illness may easily cost £20–£50, and its treatment £100–£200. The reduction of this expense associated with admission to a pay-bed in a voluntary hospital is chiefly due to economy in the cost of special investigations, and this is worth noting, since it is customary, but rather unfair, to blame nursing-homes for the great expense of illness. It may well be far less expensive to be ill in a nursing-home than in a private house, notably when the patient is ill enough to need some nursing by night as well as by day, but not so ill as to require the full-time services of a nurse. The real grievance of patients against the accepted method of organising charges and service in nursing-homes is that the fees payable, however high, are not intended to cover full-time service even for the crucial days following a severe operation, and the bill for the first week may well be swelled by a charge of 6 to 8 guineas for "special nursing." This custom applies also to patients in private rooms in hospitals, and a welcome reform would be the introduction of a weekly charge to include all nursing deemed necessary by the matron or the medical man in charge. The fees to include ordinary nursing attention payable in hospital private beds and in nursing-homes overlap to the extent that most nursing-homes have rooms available at 8 and 9 guineas a week and that pay-beds cost 3 to 10 guineas a week, while in at least five hospitals, according to the current edition of the Hospitals Year Book, private rooms are available at 12 guineas a week.

Among the biggest and therefore most dreaded expenses of illness, however, are the fees due to specialists, and it is here that a patient in a pay-bed may save a good deal. Outside the hospital the professional man has to give much of his personal attention and time to the details of management of any patient under his care. In a pay-bed he will be assisted in this respect by his resident medical officer, and therefore he can afford to be available for consultation, when required, for a smaller fee. Moreover, having more patients in one building and that building being in close proximity to his hospital wards, he can economise the time otherwise spent in going from one patient's house or nursing-home to another. Even more important than these considerations may be the fact that the specialist's habit of giving voluntary service to the sick poor affects his attitude to the patients under his care in the neighbouring paying block, and he is more inclined to charge a very much reduced or even a nominal fee for the work he does there. This applies also and to an even greater extent to the special investigations, because the plant required, whether biochemical, pathological, or radiological, is readily accessible, being provided by the voluntary hospital for its ordinary patients and thus available for paying patients of small means at cost or little more than cost price for each investigation done. The charges payable for such services by patients able to pay 12 guineas a week for a room should, of course, be maintained at the level normally payable outside the hospital, whatever the adjustment decided on as to the proportion to be kept by hospital and specialist. Specialists gain something from the possibility of accepting modest fees from patients who wish to pay their consultants but are unable to do so when admitted to the general wards reserved for the sick poor. Moreover, apart from the convenience of having many patients aggregated under one roof, they are able to keep patients under their care with whom they might otherwise lose touch.

Lastly the point of view of the voluntary hospitals is to be recalled. It is obviously their duty to provide a service for a social class which particularly needs it. The wants of the sick poor are being increasingly well provided for, but to those with limited incomes sickness brings a financial embarrassment for which it is difficult to make adequate provision. Good work done in a pay block will moreover bring gratitude to the institution that provides the beds, and this will increase the public support on which voluntary hospitals largely depend. There is of course another aspect for the patient. It is difficult to assess the comparative advantages and disadvantages of institutional treatment. Expense is often a determining factor in sickness and ill-health, but economy and efficiency do not necessarily go hand in hand, and while there are advantages in being in an institution where a resident medical officer is available, there are counter-advantages in being

the prejudice that often sets the advocates of "clinical" and "laboratory" methods in opposite camps. The X ray tube is no less "clinical" than the thermometer and the sphygmomanometer, it is only more expensive; but it is becoming increasingly accessible, and should be used neither more nor less than is justified by the greater value and precision of the results it gives.

THYROTOXICOSIS WITH NORMAL B.M.R.

When goitre is of long standing the circulatory apparatus may be considerably damaged though the basal metabolic rate is not above normal limits. Even in young patients, however, good evidence of thyrotoxicosis—such as tachycardia, alterations in blood pressure, loss of weight, nervous symptoms, and ocular changes—may coexist with a B.M.R. within the accepted upper limit of plus 15 per cent. The possibility here arises that the figures obtained, while within the average normal range, may yet be high for the individuals concerned, and would fall with iodine administration or after operation. S. Gordon and R. R. Graham[1] report 71 cases of toxic goitre with normal metabolic rates—those with nodular goitre predominating, as might be expected. Partial bilateral thyroidectomy was done in 65 (incidentally without a death) and cure or improvement was noted in about 90 per cent. of these; but the average drop in the metabolism was only 2 per cent. in the diffuse goitres and 5 per cent. in the nodular. These figures are robbed of some significance, since the times elapsing between operation and the tests are not given, and more details of particular cases would have been welcome. There is little doubt, however, that the clinical picture to which attention is drawn—namely, thyrotoxicosis associated with a metabolism within the normal and little or not at all lowered by thyroidectomy—is not very unusual. It is one that seems to call for further study.

HEALTH OF THE ROYAL NAVY FOR 1933

The first report by the new Medical Director of the Navy, Surgeon Rear-Admiral R. W. B. Hall (152 pages, 2*s.* 6*d.*), contains important changes in nomenclature. The terms "insanity" and "catarrh" have been abolished, a heading for "diseases of the breast" has been added, and "scabies" will in future be included among "diseases caused by metazoan parasites." The total force in 1933 was 83,125, the number sick was 503 per 1000, 10·02 were invalided, and 2·24 died; in actual numbers 42 died from injuries, 18 from tubercle, 17 by malignant growths, 9 from pneumonia, and 12 from other respiratory diseases. Dysentery occurred in *Norfolk* during January at Trinidad, and was cured with magnesium sulphate, grs. 60, in 2 teaspoonsful of water every hour till pain had disappeared, and stovarsol afterwards, grs. 2 twice a day, to kill the cysts. Of typhoid there were 3 cases with 1 death; of 19 paratyphoid cases none was fatal. Of influenza there were 3770 cases, of which 1 died in Edinburgh. Of malaria 210 cases are reported with 2 deaths; one of these had an attack in December from which he was thought to have recovered; but in January, whilst playing football, he was struck in the abdomen by the ball, appeared little inconvenienced at the time, but died a few hours later with a ruptured spleen. It is well to use red electric light bulbs in malarial regions; they attract mosquitoes much less than the white ones. A stoker under treatment for gonorrhœa developed a gonorrhœal septicæmia and died suddenly on the nineteenth day. A marine during field training was bitten, it is supposed by an adder, on Dartmoor; he was seriously ill with shock and brawny swelling, but after vigorous treatment, strychnine and antivenene intravenously, he went back to duty in eight days. Bathing at Malta on August 30th, a man grazed his nose on the bottom. The abrasions became septic and when he reached the Red Sea he had lockjaw; there were only 12,000 units of antitetanus serum on board, and his ship was sent at once to Aden, where he died on the next afternoon of tetanus. Of tuberculosis 176 cases came to notice as against 206 in 1932. Venereal diseases were fewer than in 1932, even allowing for cases of chancroid, which are now scheduled as diseases of the generative system. During an operation on a case of perforated duodenal abscess at Malta, a small black object found was identified as an Italian bee; it was suggested that it might have been swallowed with honey and have given rise to the abscess. Carbon tetrachloride, in use for fire extinguishers, has given rise to alarming cases of anuria at a naval hospital.

ACUTE MECHANICAL OBSTRUCTION

In spite of indefatigable attempts by laboratory workers to solve the problem of intestinal obstruction, this form of abdominal crisis remains as much an enigma as it was half a century ago. A recent clinical study of acute mechanical obstruction by Amos Fey and W. R. Cubbins[1] does, however, clarify the situation as it exists to-day. They rightly say that "any observer who has waded through the mass of literature on experimental work which has appeared during the last decade will agree with the authors that certainly most of it has been fruitless and serves only to confuse us in our efforts to lessen mortality." In their review of 241 cases of mechanical obstruction (excluding external herniæ), in which there was a mortality of 42 per cent., they point out that the death-rate has not fallen in the last thirty years. Their own emphasis is chiefly laid on early relief of the obstruction—for which of course early diagnosis is essential. Pain and vomiting remain the most important and constant symptoms. The test of an enema must be very carefully done to avoid all chance of mistake, and it should be recognised that some result from an enema is no contra-indication to surgery unless the patient is relieved subjectively. Physical signs, as most authorities have shown, are not very striking. Though distension usually increases with the duration of the obstruction, there were in this series some cases of complete obstruction with gangrene but with little distension. On the other hand, tenderness on palpation may be present more often than one would gather from surgical text-books. An abdominal finding of great importance is increased peristaltic activity revealed by auscultation; the violent contractions of the bowel are an attempt to force the bowel contents onward, and when they cease as a result of exhaustion the outlook becomes serious. Cessation of peristalsis nearly always occurs with the onset of gangrene and usually precedes it. Writing on treatment Fey and Cubbins comment on the numerous recommendations of enterostomy that have appeared during the last fifteen years; one is led to believe, they say, that enterostomy is a definite and distinct life-saving procedure, for it is often advised without mention of any attempt to relieve the obstruction. Their own records do not support this contention; the mortality of enterostomy is high, and it does not prevent gangrene unless the mechanical obstruction be relieved at the same time. Justification is provided also for another view, long held by many English surgeons, but not generally accepted—namely, that acute intestinal obstruction with gangrene is best treated by resection; exteriorisation and gun-barrel fistula, so attractive as emergency measures, have a higher mortality. Important factors in the high death-rate from enterostomy are infection of the abdominal wall and peritoneum, digestion of the abdominal parietes, exhaustion and starvation from loss of intestinal contents, and the secondary operations necessary for closure. Far too many surgeons seem to accept it as the operation of choice when obstruction has resulted in gangrene, the suggestion being that the patients are too ill to stand anything more drastic. This paper points out the error and danger of such an assumption.

SIR JAMES MICHELLI

WITH the death of Sir James Michelli on April 3rd there passes a figure well known to the medical profession. For forty years, from 1887 to 1927, Michelli served as secretary to the Seamen's Hospital Society—a record probably unique in the annals of hospital administration—and he came to Greenwich with six years' experience as secretary of St. Mary's Hospital, Paddington. Since 1927 as hon. treasurer he had retained his association with the great charity which he served so long and faithfully. When Michelli joined the Seamen's Hospital Society in 1887 its resources were at a low ebb, and the establishment consisted solely of the "Dreadnought" at Greenwich, already a time-worn institution and badly in need of repair. Under his guidance and largely owing to his inspiration, the work of the society increased to such an extent that at the time of his death it was responsible for the management and maintenance of four hospitals, a sanatorium at Bramshott, and a convalescent home at Cudham. This expansion entailed a corresponding increase of income from subscriptions, and it is said that the assets of the society increased tenfold during Michelli's administration. But his chief and most lasting work was surely the institution of tropical medicine as a factor in the medical education of this country, and this came about as the result of his close association with Sir Patrick Manson and Mr. Joseph Chamberlain. The Royal Albert Dock Hospital was built in 1887 and there, in the early nineties, he came under the influence of Manson and had the sagacity to discern the importance of his researches into malaria; and it was to Michelli that Manson first expounded his plan for the institution of a school of tropical medicine in London, with the result and owing to his energy that the school opened its doors to students in 1899. From that time Michelli was the pivot in the development of tropical medicine. He was responsible for the raising of the Chamberlain and the Milner Funds, making together a quarter of a million sterling, to further the aims of this specialty in London. And he was instrumental in the final inauguration of the new school in 1924. Born in Cork, where his father was Austrian consul, Michelli possessed in high degree the lovable qualities of the country of his birth. He was a good mixer, and he shared with the late Lord Knutsford the distinction of being the "Prince of Beggars." He continued indeed to beg so persistently and so firmly that few, if any, could be found to resist him. He was a familiar figure at almost every public function, and was always to be found dodging in and out of Government departments and other places where he thought he could obtain sympathy and material support for the objects which he had so dearly at heart. The welfare of seamen was his hobby and his sole aim.

A CHRONICLE OF CHILD WELFARE

THE student of child welfare should be grateful to Dr. McCleary [1] for having sifted so carefully such an enormous volume of facts and theories, and presented them in compassable form. Some dozen of the 14 chapters in his book are mainly historical, and certain of the records are of peculiar interest. This is, we believe, the first time that any writer has taken the trouble to select from the original reports in the *Times* the salient points in the history of Margaret Waters, the notorious baby-farmer who, in 1870, was tried and executed for murder of the infants committed to her charge. This case created a great sensation, and, together with a similar one relating to a woman named Mary Hall, doubtless had considerable influence in securing support for the efforts of Dr. J. B. Curgenven and others which eventually led to the passing of the first Infant Life Protection Act in 1872. A chapter bearing the prosaic title "How the State Recognition of Midwives was secured" sets out a story full of romance and heroism. It describes the efforts of such men as Ambroise Paré, the Chamberlens, and others who gradually lifted the practice of obstetrics from its despised estate. In the nineteenth century, when puerperal fever was still taking a desperate toll of mothers' lives, other pioneers arose who refused to be satisfied with attributing a maternal mortality which sometimes reached 200 per 1000 live births to such vague causes as "epidemic influence" or "atmospheric conditions." The author tells how Oliver Wendell Holmes in America and Ignaz Semmelweis in Vienna faced the embittered attacks of unenlightened contemporaries for their courage in publishing evidence of the communicable nature of puerperal fever. Holmes considered the doing of this "humble office" sufficient cause "to be thankful that I have lived, though nothing else good should ever come of my life." Although Semmelweis was less fitted than Holmes to contend with the onslaughts of his opponents, and died in a mental hospital, he demonstrated, by his own carefully controlled experiments, the nature of puerperal fever, and rightly merits the place which Dr. McCleary accords him as "one of the great figures in the history of medicine."

HOMICIDE

A RECENT study of homicide statistics, conducted by two officials of the Metropolitan Life Insurance Company of New York, explores the unenviable record of the United States as the only important country to show more homicides in post-war than in pre-war years. The authors have considered questions of sex, age and geography, seasons, occupations and economic cycles. Few solid conclusions emerge. The motives of murder are manifold and the personal histories of the criminals and their victims are seldom fully known. Two points are clear. First, a remarkable number of American homicides is due to the use of firearms. The proportion of firearm homicides to the general total in the U.S.A. is roughly two-thirds; in England and Wales where, apart from any difference in national habits, there are statutory restrictions on the purchase and possession of firearms, the corresponding percentage is as low as 13. Secondly, the American statistics confirm the belief that the murderer is not usually a member of the criminal classes. Evidence of their previous careers may be inadequate, but it is stated that, roughly, 75 per cent. of the men and 90 per cent. of the women charged with murder in the U.S.A. were first offenders. Homicide indeed is largely unpremeditated.

[1] The Maternity and Child Welfare Movement. By G. F. McCleary, M.D., D.P.H. London: P. S. King and Son, Ltd. 1935. Pp. 227. 7s. 6d.

Similar investigation of the incidence of murder is possible in England. We have the excellent Criminal Statistics annually published by the Home Office, the copious evidence given before the Select Committee on Capital Punishment in 1930, and the Command Paper (No. 1787 of 1922) which, at a time when the public was concerned at the number of unsolved murder mysteries, gave a reassuring account based on the comparative figures for the two-year periods immediately before and after the war. From these sources we can learn many facts—that murder, for instance, is almost exclusively a masculine offence, or that a multiple murderer often commits suicide. We have our problems also. Are we satisfied that capital punishment is a deterrent, that mental instability is sufficiently understood in criminal courts, that indiscriminate publicity is desirable for murder trials, and that no better classification of the degrees of homicide can be evolved?

WHAT IS ADDICTION?

ADDRESSING the Society for the Study of Inebriety last Tuesday Dr. W. E. Adams pointed out that the word "addiction," as applied to drugs, is of comparatively recent origin. Its implication is that the addict is bound to a master, and it is thus peculiarly applicable to the state induced by habitual use of such drugs as morphine, heroin, and cocaine. Once a man admits one of these into his life it, and not he, will be the master. This is one prime characteristic of addiction, said Dr. Adams; another is connected with the motive which prompts resort to drug-taking. Generally speaking, and in western countries, this motive is the need for some agent which will temper the wind of reality to the psychically shorn lamb; for the victims of addiction are, almost always, not quite normal psychically. A third feature is the development of what is known as "craving"—an urgent need for the continuance of the drug. On its being withheld there is a distressing train of symptoms, both physical and mental. Also, in cases of true addiction, we have a "tolerance" or a gradual accustoming of the tissues whereby the seasoned addict is enabled safely to take doses of a magnitude that earlier would have speedily ended his life. Lastly the masterful character of the drug is shown by any almost uncontrollable tendency to revert again to it after apparent cure. Thus addiction, said Dr. Adams, may be defined as a state of bondage to a masterful drug usually, but not always, of the narcotic class, and manifested by craving, tolerance, intense discomfort of a specialised character on withdrawal of the drug, and a tendency to relapse. Its origin lies in a defect of the personality which may be of varied kind, but is most commonly of the nature of an inability to cope with reality. These criteria may usefully be applied to certain doubtful forms of addiction—e.g., tobacco-smoking and tea-drinking. Neither tea nor tobacco has the dominating character of opium, morphine, or cocaine, and the like; but if the personality be weak they may be powerful by comparison, and in certain circumstances either of them may produce all the stigmata of a true addiction.

COMMON SALT IN ADDISON'S DISEASE

WE have already reviewed the work upon which the use of sodium chloride in Addison's disease depends, and also some records of therapeutic success.[1] Conclusive evidence on the relative value of sodium chloride and cortical extract, and on the relative importance of the sodium and chlorine ions and their relationship to other mineral elements is still awaited. M. A. Blankenhorn and J. M. Hayman[2] have recently recorded the successful treatment of a patient in crisis with intravenous sodium chloride when cortical extract alone had apparently failed. In the subacute phases of the disease, salt by mouth was adequate to maintain a relatively good condition; and for a period of 17 days the daily dose of 12 g. NaCl was replaced by a mixture of Na_2SO_4, Na_3PO_4, and Na_2CO_3, in amounts that contained an equal quantity of sodium. Several interesting questions arise from this communication. Although, according to A. M. Snell,[3] cortical extract alone may be effective in Addisonian crisis, most observers, notably Rowntree and his collaborators, and Levy Simpson, have urged the additional use of intravenous saline, this being a more direct way of remedying dehydration and blood concentration. To rely only on fluids and salt in crisis might jeopardise the life of the patient unnecessarily when a potent cortical extract is available. In the treatment of the more chronic phase of the disease, it is yet to be determined whether the use of salt alone, in preference to potent cortical extract, has anything to recommend it other than its great cheapness and the fact that it is effective when given by the mouth; this is not to minimise the enormous importance in clinical medicine of these two considerations. The patient described by Blankenhorn and Hayman was treated for the greater part of the time with salt only, and died after five months. R. F. Loeb and D. W. Atchley stated[4] that "salt-treated patients retain most of their pigmentation, they are sensitive to cold and tire more easily than normal individuals, and the systolic blood pressure, while definitely above shock levels, tends to be low, as does the concentration of sugar in the blood;" and that salt feeding will not maintain life for more than three weeks in completely adrenalectomised animals. Loeb emphasised the loss of sodium as an essential factor in adrenal insufficiency, and the fact that Blankenhorn and Hayman were able to replace the chloride by less nauseating salts of sodium is both of theoretical and practical interest.

In considering whether the low level of serum sodium can be correlated with the symptomatology of Addison's disease, other mineral elements come into consideration. Loeb and Atchley found that "the potassium content of the blood which is elevated to varying degrees in acute insufficiency of the adrenal glands returns to normal levels with salt administration." Urechia, Dragomir, and Retezeanu have found that cortical extract reduces the high concentration of blood potassium in a patient with Addison's disease to normal levels.[5] They also suggest that the high toxicity of ionisable potassium and the selective action of this poison on the muscles, explain very well the asthenia associated with its retention. It would appear that there is still much to be learnt about mineral and water balance in adrenal insufficiency, and the inadvisability of limiting such investigations to chloride or sodium is clear.

SNAKES AFTER DINNER

MEMBERS of the Hunterian Society, assembled for their annual general meeting last Monday at Simpson's Restaurant, Cheapside, were looking forward to an after-dinner lecture by Lieut.-Colonel R. H. Elliot, F.R.C.S., on snakes and their bites. At the last moment a sudden indisposition prevented Colonel Elliot from being present and Mr. Mortimer Woolf, the society's librarian, was faced with the unexpected task of demonstrating the slides and cinematograph film that were to have accompanied the lecture. With the expert assistance of Dr. Burgess Barnett, curator of reptiles at the London Zoo, he at least made the audience aware of the fascinating nature of the lecture they had missed. Slides were shown illustrating the mechanism of snake-bite, the evolutionary development of the poison-fangs, and the methods used for extracting the venom from snakes for the production of anti-snake bite sera; but in the absence of the lecturer even more interest attached to the remarkable film taken by Captain Newnham Deane at the snake farm of the Butantan Antivenine Institute, Brazil. There, in a wooded enclosure, fenced by a snake-proof wall and moat, were to be seen hundreds of snakes awaiting "milking." Local farmers are encouraged to send all snakes they may encounter to the institute, with the result that a useful species that feeds on the dreaded fer-de-lance was much in evidence in the film; it was shown first eating and then being compelled to regurgitate its prey which seemed little the worse for the experience. Walking unconcernedly among them an attendant picked the snakes from the ground or raked them from trees to extract their venom into a Petri's dish—venom which is valued at £60 an ounce. The cordial reception given to the film, and the expressions of gratitude to Dr. Barnett, left no doubt of the success of the valiant efforts made to save the evening from disaster.

SERUM TREATMENT OF CEREBRO-SPINAL FEVER

SKIN reactions following the intradermal inoculation of filtrates of fifteen-day broth cultures of meningococci were first described by Erlich, Popowski, and Przesmycki in 1925.[1] Six years later Ferry, Norton, and Steele [2] confirmed this observation by obtaining similar reactions in human beings following the intradermal inoculation of filtrates of four to six days broth cultures of meningococci of all types. From further investigation Ferry [3] [4] has since concluded that filtrates of broth cultures of meningococci contain a diffusible toxin, and that antitoxic sera may be elaborated for all types of meningococci by the inoculation of horses with the respective filtrates. A polyvalent antitoxic serum obtained from Ferry's filtrates has now been provided for therapeutic purposes and the paper by Dr. Banks in our present issue contains a record of the first clinical trial of this serum in England. As Banks points out, the number of cases treated with this antitoxic serum in England (25 in all, with 7 deaths) is too few to enable any conclusions to be drawn about the relative therapeutic merits of the antitoxic serum and the "antibacterial" serum now in general use. The results reported by American clinicians certainly seem to show that the antitoxic serum is the more active. Thus Hoyne,[5] of the Cook County Hospital, Chicago, reports that death occurred in 20 out of 85 cases of cerebro-spinal fever treated with polyvalent meningococcal antitoxic serum, whereas 96 died out of 211 treated with the usual polyvalent antibacterial serum. It is important to note, however, that in 40 of the cases quoted by Hoyne bacteriological diagnosis was not made. On the whole the time has probably not come for the general adoption of the antitoxic serum as a method of treatment in this country. More controlled clinical research is required, and owing to the fortunately low incidence of the disease in England this will necessarily take some time.

From the bacteriologist's point of view the position is equally uncertain. In the first place, it is not yet clear whether the filtrates of meningococcal broth cultures contain anything other than the products of the very rapid autolysis of the organism. Substances poisonous to guinea-pigs on subdural inoculation undoubtedly occur in the filtrates, but they also occur in filtrates of other neisseriæ grown under the same conditions. Secondly, the appearance of the poisonous substances in the broth cultures is paralleled by the development of products of bacterial destruction such as precipitinogens. Again, protection experiments on animals with antitoxic sera provided by Ferry and with antitoxic sera made from English strains of meningococci have not yet confirmed the happy results obtained by the American workers. Finally, with regard to the therapeutic antitoxic serum itself, it must be pointed out that the system of arbitrary units adopted by its manufacturers is one which is not acceptable to English bacteriologists, and practitioners would do well to view critically statements concerning units which are not admitted by the Standards authorities of this country.

WE regret to announce the death from pneumonia on April 7th of Dr. John Braxton Hicks, M.R.C.P., at the age of 50. Dr. Braxton Hicks was pathologist in charge of the L.C.C. group laboratory at Lambeth.

Summer Time, which has already been in force a fortnight in France, will commence in Great Britain, Ireland, the Channel Islands, and the Isle of Man on Sunday morning next, April 14th, at 2 A.M., when the hands of timepieces should be advanced one hour. It will end on Sunday, Oct. 6th.

A SCHOLARSHIP of £200, open only to the sons of medical men, and tenable at St. Bartholomew's Hospital Medical College, will be offered for competition on May 27th. The scholarship will be confined to candidates who have passed London Matriculation, or obtained exemption from it. The examination will be conducted in (1) English; (2) French or German; (3) mathematics; (4) two other selected subjects, and the standard will be similar to that of Matriculation. Intending candidates should apply for further information about this Helen Cave Memorial Scholarship from the Dean of the Medical College, St. Bartholomew's Hospital, London, E.C.1, before May 1st.

MANSFIELD HOSPITAL.—An appeal for £10,000 is being launched by this hospital in an endeavour to wipe off its overdraft and eliminate heavy interest charges.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XLVII.—PROGNOSIS IN TOXIC GOITRE

If the natural course of a disease is known, and also the extent to which this can be altered by treatment, the prognosis can be stated with confidence, due consideration being given to the variations in constitution, temperament, and environment that are found in patients. In toxic goitre the course of the disease is extremely variable, and the personal and environmental conditions of the individual patient affect the course and possibilities of treatment to such an extent that the principles that guide the formulation of a prognosis cannot be stated briefly.

NATURAL COURSE OF THE DISEASE

Although the cause of the disease is unknown, the onset and the relapses are so frequently associated with certain events such as acute infections, especially acute tonsillitis, and mental strain and worries, that these must be regarded as ætiological factors. In a small number of patients in whom the onset is associated with a definite factor of this nature the disease may be of brief duration and after a course lasting a few months end in complete recovery. This short course appears to be related to the cessation or removal of a definite causal factor. The complete resolution of an acute tonsillitis, the enucleation of infected tonsils, and the satisfactory solution of a worrying financial situation or love affair may be quoted as examples. The presence of a definite ætiological factor and the possibility of removing this factor thus favours a short course and good recovery.

The more usual course is a long one continuing with remissions and relapses over a period of many years, and this must be expected if rapid recovery does not occur in a few months. Once the disease is clearly established complete recovery is improbable. A remission may last for many months or even years, during which the symptoms and signs of the disease may be barely perceptible, but a relapse may occur at any time and although such a relapse may be mild it may, on the other hand, be so severe as to cause death. Events of ordinary life, which scarcely affect the health of normal people, disturb these patients profoundly. If they can be guarded and their lives steered through calm waters they may continue for many years with moderately impaired efficiency. Sooner or later, however, the strain on their organs and tissues causes more definite disturbances of function, and a common sequel is auricular fibrillation with congestive heart failure that threatens life. Less often it is the mental faculties that give way. If a life of constant strain or repeated worries is inevitable the disease is likely to be more severe, and the onset of circulatory or mental troubles earlier.

In young women who have for many years suffered from vague ill-health with an appearance of anæmia, with constipation, various visceral neuroses, and lack of energy, there may arise at some point in their history symptoms of toxic goitre: tachycardia, tremors, nervousness, and a slight enlargement of the thyroid gland. The toxic goitre in these patients is usually mild and continues for many years, but it is only one factor in the disability and, as a rule, not the most potent factor. From the prognostic aspect this is an important group to recognise, for the results of treatment directed to the thyroid gland are disappointing and such treatment alone cannot be expected greatly to improve efficiency.

EFFECT OF TREATMENT ON THE COURSE OF THE DISEASE

There are two main lines of treatment whereby the course may be affected: (*a*) rest and removal of sources of infection or of worries and mental strain, and (*b*) diminishing the amount of functioning thyroid gland tissue.

(*a*) As soon as the diagnosis is made, treatment by rest must be instituted, and this should be carried out in an environment other than that associated with the onset. The accessory factors such as infected tonsils, teeth, and sinuses, and mental stresses, especially financial, family, and marital, must be weighed and dealt with if possible. If the disease is of short duration previous to the commencement of treatment, and a rapid improvement takes place, it is possible that recovery will be complete enough for a return to normal life and activities. If the disease has already been present for some years or if the improvement is not so satisfactory a chronic course of remissions, relapses, and ill-health is probable, and a life of even moderate efficiency and happiness is only possible under placid and protected conditions. In addition there will be an ever-present danger of a serious relapse that threatens life. The presence of a nodular thyroid gland is evidence of a repeated or prolonged disturbance of the functions of the gland and points to the probability of incomplete recovery and continuing relapses.

(*b*) Removal or destruction of a sufficient amount of the functioning tissue of the thyroid gland by means of surgical operation or irradiation will prevent the occurrence of the severer grades of intoxication, so that the danger of a relapse that threatens life is thereby removed. To effect this by irradiation takes several months at least and the results are uncertain. In the more severe cases the possible onset of dangerous relapses and complications, circulatory or mental, during these months of treatment must be considered. On the other hand, there is a danger to life as an immediate result of the operation of thyroidectomy. In the hands of surgeons experienced in operations on the thyroid gland this danger is negligible in uncomplicated cases, but in the hands of those who are not especially expert or experienced the danger is a real one and must be carefully weighed. Whenever possible operation should be delayed until a remission has set in. Careful selection of the most favourable time for operating and the administration of iodine cannot eliminate entirely this immediate danger.

Adequate treatment by surgery or irradiation can also restore the efficiency of the patient. Following sub-total thyroidectomy a return to normal activities can be expected at the end of three or four months. In many cases recovery is complete and all symptoms disappear, but mostly there remains some slight degree of excessive or of lowered activity of the gland, so that it is usually advisable for such a patient to avoid the more strenuous types of mental and physical exertion; but for all ordinary purposes the outlook for functional efficiency is good. To some extent it will depend on the possibility of avoiding the accessory ætiological factors already mentioned; an unhappy marriage, for example, will affect the prognosis adversely. From a review of the results of treatment after ten to fifteen years, the patients in whom a slight degree of hyperactivity persists appear to be happier and more efficient than those in whom a mild hypothyroidism has developed;

the administration of thyroid gland cannot be relied upon to compensate accurately for the deficiency.

In the type of case referred to above, in which the thyroid disturbance is but part of a general condition of ill-health, often of many years' duration, the general improvement resulting from treatment for the thyroid condition, including surgical treatment, is disappointing, and many such patients are more unhappy and inefficient after operative treatment than before. The prognosis in these cases will necessarily depend upon the relative importance of the thyroid in the disability of the patient. Even after sub-total thyroidectomy relapses requiring further treatment by operation or irradiation do occur, but these must be regarded as exceptional.

Use of iodine.—The reintroduction of the use of iodine in the treatment of toxic goitre has affected the the prognosis profoundly in that it has rendered the operation of thyroidectomy much less dangerous to life. It is probable also that by its aid the patient's readjustment following operation is easier and his ultimate efficiency increased. The value of iodine in diminishing the severity of relapses and in aiding in the establishment of remissions is also undoubted, but it probably has no effect on the ultimate course of the disease other than to diminish its severity, and it is doubtful if operative treatment can be avoided by its administration or if complete recovery can ever be accounted to it. If the disease is increasing in severity the remission that results from iodine is temporary, but if iodine treatment coincides with a natural remission the effect is prolonged. If operative treatment must be carried out before a natural remission sets in, the temporary iodine remission is the safest time in which to operate.

PROGNOSIS IN SPECIAL CIRCUMSTANCES

Circulatory disturbances.—Extrasystoles and auricular fibrillation, at first paroxysmal but later established, are commonly found in elderly patients with toxic goitre, even in quite mild grades of hyperthyroidism if the disease is of long standing; they occur also in younger subjects if the disease is severe. These disturbances of cardiac rhythm are a strong indication for treatment by thyroidectomy, and they and their effects upon the circulation disappear spontaneously in most cases with the improvement in the toxic goitre that follows successful treatment. In some patients the administration of quinidine is necessary before normal rhythm is restored. In a small number of cases the auricular fibrillation persists in spite of all treatment, and in these the ventricular rate must be controlled with digitalis; in many of these some other form of heart disease is present. A raised blood pressure is met with in toxic goitre, especially in elderly patients, which disappears or becomes less pronounced after recovery. In others it persists even after successful treatment. This condition should be regarded as an indication for diminishing the amount of functioning gland tissue so that the heart may be relieved as much as possible from extra and remediable stress.

Mental disturbances.—Although more frequent in middle-aged and elderly patients, serious disturbances may be encountered in young girls with severe hyperthyroidism. Prognosis must depend upon a careful evaluation of hereditary and familial factors, but in most instances it clears up following thyroidectomy, though there may be a period of greatly increased severity for some months following the operation, a period of great distress and anxiety to the relatives. In general, such disturbances should be regarded as an indication for operation rather than the reverse, but much care and consideration must be exercised before deciding on this line of treatment.

Glycosuria.—Disturbances of carbohydrate metabolism with diminished sugar tolerance and glycosuria are not uncommon, and may be of varying degrees independent of the severity of the thyroid disturbance. They are usually mild and disappear with the subsidence of the thyroid disease. They may persist though diminished in severity, and require continuous treatment as for diabetes mellitus, but are seldom progressive.

Amenorrhœa.—During the course of toxic goitre amenorrhœa is commonly found and pregnancy seldom occurs. Following recovery menstruation is re-established and successful pregnancies are frequently met with.

Proptosis.—Of all the symptoms of toxic goitre exophthalmos is the most persistent. Although a considerable diminution in the degree of proptosis slowly follows successful treatment for the toxic goitre and sometimes it disappears completely, some degree may persist indefinitely, and it is usual to recognise a brightness of the eyes or slight staring for many years.

Toxic goitre in childhood.—In children the disease may follow a stormy course and prove fatal unless treatment by thyroidectomy is carried out before the operative risks are too great. The principles of prognosis are essentially the same as in adults, but in the milder cases treatment by rest and general measures may be persisted in for a longer period, for the probable course of the disease can be foreseen with even less confidence. Moreover, since profound changes take place in the glands of internal secretion at adolescence, the effects of drastic treatment of the thyroid gland before this period upon health, character, and temperament cannot be gauged. These patients require to be under careful observation for many years, and such measures as ligation of arteries and treatment by X rays have proved of value in guiding them to adult life and health.

Pregnancy.—During pregnancy the disease usually improves, but there is not infrequently a relapse in the puerperium. A relapse is usual if the pregnancy is terminated artificially, and may then be severe. It is better to carry the pregnancy through to term. If the severity of the toxic goitre is endangering the life of the mother, partial thyroidectomy should be performed and the pregnancy allowed to continue.

SUMMARY

Toxic goitre is usually a chronic disease that may endanger life, and seriously lowers efficiency. The danger to life can be removed by diminishing the amount of functioning thyroid gland tissue by means of surgical operation or by irradiation. The most efficient method of doing this at present is by surgical operation. This operation may be dangerous to life, and the mortality is negligible only in the hands of surgeons especially skilled and experienced in operations on the thyroid gland.

Efficiency is frequently restored by treatment, but some slight disability commonly persists. Patients with a mild degree of persisting hyperthyroidism are more happy and efficient than those with hypothyroidism.

The result of treatment directed to the thyroid disturbance will depend on the degree to which the thyroid disturbance accounts for the disability of the patient; toxic goitre frequently arises in the course of chronic ill-health and is but one factor in the disability.

MINOR EPIDEMICS OF "INFLUENZA"

(EPIDEMIC CATARRH)

A CLINICAL STUDY OF NINE SEASONS, 1924–33

By G. M. Wauchope, M.D., M.R.C.P. Lond.

ASSISTANT PHYSICIAN TO THE NEW SUSSEX HOSPITAL, BRIGHTON

It has been said that "no one has yet succeeded in achieving either a satisfactory definition of what is meant by influenza, or a description, far less a regulation, of the usage of the word."[1] Epidemiologists are not agreed upon which of the prevailing illnesses of the past were influenza; purists decline to accept any epidemic unless a recognised causative organism (such as Pfeiffer's bacillus) is isolated; clinicians consider only the great pandemics as the true disease. The general practitioner, however, calls all the catarrhal fevers with which he has to deal in the winter months "influenza."

There are four criteria by which this "influenza" or epidemic catarrh is distinguished.

(1) The illness is acute and catarrhal, affecting the mucous membranes of the respiratory tract and less frequently of the digestive tract.

(2) There are pronounced symptoms but the physical signs are negligible.

(3) There is almost always a sudden rise of temperature. Apyrexial cases do occur but are rare and are not diagnosed as influenza unless they are associated with ordinary febrile cases.[2]

(4) Similar symptoms are shown by a large number of people.

These conditions are fulfilled by the minor epidemics or "prevalences" which are seen almost annually. They have been described in closed communities such as schools and ships by Dukes, Simey, and Dudley, whose results were summarised by Glover in 1932 from the epidemiological aspect.[3] General practice affords an opportunity to study them clinically among the people at large, and it is remarkable to find that although the circumstances of the patients vary widely yet each season's illness has its own individual peculiarities.

Dudley noted that in one epidemic, batches of patients from the same ship presented the same clinical picture, which differed from that in other ships, and that the boys of Greenwich School had the same type of epidemic in four different years although among the population outside there was pleomorphism.[4] In this series, however, the characteristic features seemed to follow the year.

The Nine Epidemics

Nine winters are reviewed, the last being that of 1932–33; the winter of 1933–34 is not included because the cases of feverish catarrh were so few and so scattered that a diagnosis of "influenza" was not made.

The practice in which the 584 cases occurred is in a large seaside town and the majority of the patients were women and children; all ages up to 80 are included but a large proportion (30·4 per cent.) were children under 14 years of age.

INCIDENCE

The incidence of the illness for each winter has been set out in Charts 1–9. They give a rough[*] idea of the relative proportions of the epidemics and from them certain broad generalisations can be made.

(1) There were three types of chart: the first with a sharp peak, the second with a broad irregular mountain, and the third with a low plateau. In the years with the first two types of chart the number of cases was about the same from year to year, averaging 86, but in the plateau years there were only about a quarter that number (average 22).

The sharp increase in the cases to a maximum and the slower fall is characteristic of epidemic influenza,[5] and in the years with this type of chart there were extensive epidemics in Europe and North America as recorded by D. and R. Thomson.[5] The more gradual increase extended over several weeks and giving rise to charts of the second type occurred locally in milder epidemics, but in these years also there were widespread epidemics except in 1931–32 when the local chart shows the least "peak" of any. On the other hand, in the years with the local "plateau"-shaped chart there was no recorded influenza in Europe or America and the illness of these years might more properly be called "sporadic catarrh"; they have been included because individual cases presented symptoms and evolution similar to the "influenza" of the other epidemics, and even included cases without respiratory catarrh.

(2) In each of the years under review there was a small outcrop of cases in the autumn, then a clear month, generally November, but on three occasions December or January, followed by a great increase in the number of cases between the end of January and the end of February. One week often accounted for a high peak of incidence.

(3) A third point which emerges from the charts is the similarity of the time distribution in each succeeding year. September and May were the limits, and the peak, when there was one, fell within the four weeks between the end of the third week in January and the end of the third week in February.

CLINICAL DESCRIPTION

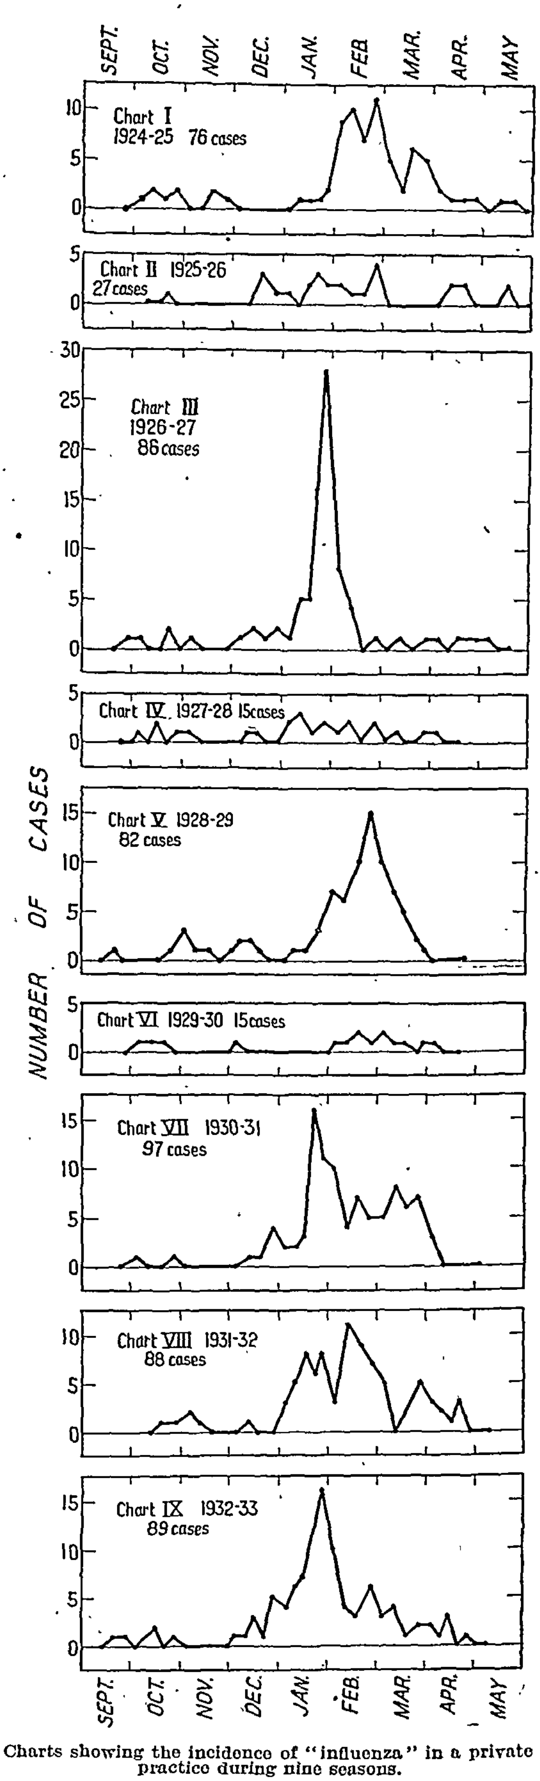
Analysis of the notes taken at the bedside reveals that there were three distinct *types of the illness* which occurred either alone or in combination one with another: (*a*) respiratory, (*b*) alimentary, and (*c*) neuromuscular.

(*a*) *Respiratory catarrh* was the prevailing disorder in over 80 per cent. of the cases in each year under review, the average being 88 per cent.[†] The symptoms in uncomplicated cases were those of a severe cold in the head, sneezing, suffused eyes, and incessant mucoid nasal discharge which reddened and excoriated the nostrils and upper lip. The throat was sore in about 20 per cent. of all cases, but the most characteristic feature was a hard barking cough persisting day and night in over 50 per cent. of the cases. Paroxysmal sneezing occurred in the epidemics where nasal catarrh was marked, and epistaxis in the same type of illness. Injection of the pharynx was the only objective sign except for occasional scattered rhonchi in the lungs.

---

[*] For instance, Chart 3, 1926–27, shows an artificially sudden fall due to the illness of both partners on the same day (Feb. 5th); cases were transferred and notes lost. The growth of the practice affords another fallacy so that the 89 cases of 1932–33 are not nearly so high a proportion of the cases seen during the year as the 86 cases of 1926–27.

[†] This comprises all cases with respiratory symptoms, whether alone or in association with the other types.



Charts showing the incidence of "influenza" in a private practice during nine seasons.

The cough was probably due to extension of the pharyngitis to the trachea. There were 68 cases without respiratory catarrh and these were divided almost equally between the alimentary (31, or 5·5 per cent. of the whole) and the neuromuscular (37, or 6·5 per cent.) types of the illness.

(*b*) In the *alimentary type* the symptoms were diarrhœa and vomiting, intense nausea, flatulence and epigastric discomfort, and, in a few cases, severe abdominal pain (9 out of 31 pure alimentary cases). There was sometimes a close imitation of an acute surgical condition, but it did not give rise to real difficulty in diagnosis since the cases occurred in an epidemic.

98 cases, or 17 per cent. of the total, had alimentary symptoms; of these, 17 combined respiratory and alimentary catarrh, and thus the series differed from Marriott's experience in 1933 at the Middlesex Hospital, where each group was quite distinct.[6]

(*c*) The *neuromuscular* group of symptoms likewise sometimes constituted the whole picture, but in other cases were combined with the respiratory or alimentary type of illness. They were headaches, sometimes described as a "tight band," pains in the limbs, back and bones—especially of the face‡ or a bruised feeling all over—and were often associated with prostration. In combination, this group of symptoms was noted in 152 cases, or 26·6 per cent. of the whole. The "pure" cases were slightly more frequent than the pure alimentary type, although none occurred in two of the years; but two other years, 1924–25 and 1926–27, accounted for more than half the total. They were years of severe illness and the neuromuscular cases were the worst.

Certain symptoms were noted occasionally in all the groups: for instance, shivering in 38 cases, chiefly at the beginning of the illness. Perspiration frequently drenched the patient on the third or fourth day. Giddiness or fainting made a dramatic onset in isolated cases in four of the epidemics, but in 1930–31 was commoner (7 cases). It was not necessarily a bad prognostic sign. Prostration occurred only in the severe epidemics and in severe cases; it will be further discussed in this context.

Fever was usually highest at the onset, or within at most 48 hours, and in uncomplicated cases reached normal on the fourth to the seventh day, the fifth day being the most usual. The maximum observed temperature has been analysed in 499 cases, but in some of these the highest points have probably escaped notice. In 300 (60 per cent.) the highest point was under 101° F., in 199 (32·5 per cent.) between 101° F. and 103° F., and in 37 (7·5 per cent.) over 103° F. In 4 cases under constant observation the temperature was subnormal throughout.

The height of the fever seemed to have no relation to the severity of the illness, but rather to the prevalent type; so that although it was highest in 1926–27 the most severe epidemic, the next highest was in 1927–28, one of the mildest, but having sore-throat as the presenting symptom.

COMPLICATIONS

Complications supervened in 23·2 per cent. of the cases. The most common were bronchitis, pneumonia, otitis media, and myocardial toxæmia.

Bronchitis occurred in every epidemic (64 cases, 10·9 per cent.), and was no doubt due to an extension of the respiratory catarrh from the pharynx and trachea to the bronchial tubes. It increased the length and severity of the illness but never endangered life, and at the mildest was recognised only by the presence of scattered rhonchi for a day or two and a "loosening" of the cough.

---

‡ Pain "in the bones" of the face, nose, and forehead was said to be frequent and almost pathognomonic in the epidemic of 1782. (Min. of Health. Rep. on Public Health and Med. Subjects, No. 4, p. vii.)

Pneumonia supervened as a new and serious complication. It appeared in three forms: First, ordinary lobar pneumonia which attacked three young people and one old woman on the fifth to the seventh day after the onset of "influenza." The left base was the site in three, the right in one, and the temperature fell by crisis on or about the seventh day. Two of the cases occurred in one of the mild epidemics, 1925–26. Secondly, broncho-pneumonia followed bronchitis in one case, with recovery; this and the third case of pneumonia were in a severe year—1932–33. Thirdly, toxic influenzal pneumonia occurred in three cases in 1926–27. The picture presented was quite different from that of the lobar pneumonia seen in other years, the physical signs in the lung being a very small part of the whole. Cyanosis was marked and prostration extreme; the pulse was running and feeble, and respiration weak. Two of the patients died, one on the eleventh day of the illness and seventh day of the pneumonia. The other, an old lady who had had repeated colds during the winter, was overwhelmed from the start and died on the fifth day; consolidation of the lung was appreciable on the third day.

The patient who recovered became cyanosed, with rapid pulse and respiration on the fourth day of the illness, the temperature being 102° F. Dullness at the bases, first the right and then the left, was not detected until the seventh day when the temperature had fallen to 99° F. The illness ran the usual course of influenzal pneumonia. The consolidation at the bases did not clear for five weeks and was associated with irregular low pyrexia, rapid pulse, great prostration, and pleuritic pains. Twenty million staphylococci and Friedländer's bacilli in a vaccine made from a sputum of the first patient who died were given on the eighth day with remarkable clinical improvement, and repeated in increasing doses on the eleventh and fourteenth days. The patient was convalescent eight weeks from the onset.

Otitis media was the most common complication after bronchitis (35 cases, 6 per cent.). It was observed in six out of the nine seasons but varied in severity; for instance, in one year (1928–29) suppuration occurred in all the cases, while in 1930–31 all subsided without paracentesis or spontaneous perforation. It took place in cases with respiratory catarrh on the third to the eighth day of the illness. One adult patient, in 1932–33, developed mastoiditis. All except three of the patients were children.

Myocardial weakness only appeared in five of the epidemics, affecting 14 patients; it generally developed after the first week, or well into convalescence, and presented a characteristic clinical picture. The patients lay limp in bed, flat on their backs, and were unwilling to lift a hand or raise their heads. Mental and emotional depression was extreme, and they often feared they would die. They were pale but not cyanosed; the skin was clammy, the tongue furred, and the eyes closed. The heart was generally dilated, the apex being about half an inch outside the mid-clavicular line, the right border just beyond the right edge of the sternum. The sounds were regular, but "woolly" or "tic-tac" and generally rapid, but in two cases there was bradycardia. The systolic blood pressure was very low (90–104 mm. Hg) and the pulse pressure small. The length of time taken to recover was in direct ratio to the age of the patient and ranged from ten months in a woman of 56 to four weeks in a boy of 12.

The following unusual complications were observed:

Cervical adenitis ..	2 cases in children.
Pleurisy	2 cases.
Nephritis	1 case in a child.
Phlebitis	1 case.
Sciatica	1 case.
Jaundice	1 case.
Hæmoptysis	1 case with no physical signs or sequelæ.
Fibrosis of roots of lung	1 case.

The last of these cases deserves brief notice.

In February, 1932, the patient, a woman of 40, suffered *during the second and third weeks of "influenza"* from attacks of breathlessness lasting about half an hour. Moderate and variable pyrexia persisted for two months and crepitations were heard constantly at the roots of the lungs. Radiograms taken seven weeks from the onset showed a condition which appeared to be fibrosis. The sputum was tested repeatedly for tubercle bacilli with negative results and the patient made a complete recovery after having been laid up for three months; she had influenza the next year with no complications and was back at work in a fortnight.

LENGTH OF ILLNESS AND NUMBER OF ATTACKS

The duration of disability, based on the length of time the patients were visited, is a rough measure of the severity of the illness. Obviously, some patients cast off medical attention at an earlier stage than others, while factors other than the severity of the illness influenced the time taken to recover; for instance, necessity drove some back to work too early, whereas valetudinarianism prolonged convalescence in others. But in the main the years in which the illness lasted longest were the years in which it was most severe. Of the survivors, 42 per cent. were well in less than one week; 33 per cent. in from one to two weeks; 14 per cent. took between two and four weeks; 8 per cent. one to three months; and 2 per cent. (12 patients) took over three months.

Relapse or recurrence of the illness within twenty-one days of the onset was seen in four cases, on the 7th, 9th, 13th, and 20th days respectively, and in each of them the relapse was worse than the original attack.

Second attacks developed, between one and three months after the first attack, in seven cases; the shortest interval was between Dec. 1st and 25th; the longest Oct. 30th to Feb. 2nd. The patients had all recovered and gone back to their usual life before the second attack; this was always worse than the first, and in six cases was complicated—by otitis media (1), by cardiac debility (3), of which one was further complicated by cardiac infarction, by bronchitis (1), or by relapse during the second attack (1).

Multiple attacks with intervals of eight months or more were incurred by 63 patients; the largest number for one patient was seven in the nine seasons.

(To be concluded)

SHEFFIELD ROYAL INFIRMARY.—A new operation theatre block to be named the Silver Jubilee Block is to be erected this year at the Sheffield Infirmary. In 1934 for the first time for many years the income of the infirmary exceeded its expenditure, and this money is being used to build the new block.

NEW HOSPITAL FOR BANBURY.—It is proposed to build a new hospital for Banbury and its district as the improvement of medical services, the increased readiness of patients to come into hospital, and the growth of the workpeople's hospital association has overtaxed the accommodation of the present institution.

suggested that the patient was a Mr. M., vice-chairman of the Bath City Football Club. A porter at the hospital, who knew Mr. M., confirmed the suggestion. A fellow-director of the Football Club happened to be at the hospital and had no hesitation in identifying the injured man as his colleague Mr. M. Someone having communicated with Mr. M.'s household, his father went to the hospital and recognised the patient as his son. It was not till Mr. M.'s wife arrived that the mistake was discovered. She at once declared that the man was not her husband. Later in the day the real Mr. M. came home safe and sound and the true identity of the motor-cyclist was established. Such is the force of suggestion; one person's statement persuades others. If St. George is seen upon the walls of Jerusalem by hundreds of Crusaders, there must be someone who sees him first before the crowd accepts the miracle.

It must often happen that the law is too easily satisfied with identification by witnesses who may be mistaken. When Adolf Beck was first sentenced some 40 years ago, 15 out of 17 women identified him as the man who had swindled them. When he was convicted again in 1904, 19 women identified him. But when it appeared that a judicial blunder had been committed and that the real criminal was a man named Thomas, who had been arrested on similar charges of swindling, witnesses who had identified Beck now agreed that Thomas was the man. Successful defenders like Serjeant Ballantine and Sir E. Marshall Hall have secured acquittals by producing in court somebody who closely resembled the accused man then undergoing trial; the chief witnesses for the prosecution could not distinguish one man from the other and conviction was impossible. The classical illustration of the fallibility of identification was the Tichborne litigation of the eighteen seventies. Roger Tichborne, the missing heir, had been slight and delicate, with a long narrow face and thin straight dark hair. Arthur Orton, the claimant, weighed 24 stone and had a large round face crowned with a mop of fair and rather wavy hair. A hundred witnesses recognised Orton as Roger Tichborne. The latter's mother was the most persistent in believing the impostor to be her son. Alone of her family, she had refused to believe that Roger was drowned when the ship in which he travelled foundered with all hands. She advertised for news of him, and, when the claimant came forward, she had made up her mind before she saw a line of his handwriting or heard a fact about his history. She recognised him as soon as she saw him first in a hotel bedroom on a dark afternoon in winter, and nothing could shake her faith afterwards. With Lady Tichborne the wish was father to the thought, but cases where all motive or

Association is none the less powerful in its own way, and an effective guardian of its members' interests. It began quite modestly half a century ago with the object, convivial rather than trade-unional, of bringing together every quarter the directors and editors of the medical journals. On these occasions solutions were found to problems whose discussion in the press might have been less amicable, since it is easier to agree over a glass of wine than over the printed page. The annual subscriptions covered the cost of the meals eaten, and provincial colleagues were invited to fill gaps left at the table by absentee members. After the late war, however, difficulties arose requiring more than conviviality, and from being an informal dining and debating society the Association has had to convert itself into a *syndicat*, a sort of trade-union, fighting for the interests of its members. With the devaluation of the franc and the rise in the cost of production, the medical journals have had to charge more both to subscribers and advertisers, though considerable economies have been effected by centralised purchase of raw materials and other means. A united front has also had to be shown to the collectors of taxes. The reluctant admission that the scientific and brilliant editor does not necessarily possess all the qualifications required of a successful business manager has led to a certain readjustment between the editorial and managerial departments, to the benefit of both; and here, again, the Association has oiled the wheels of progress. At its last annual meeting it appointed a technical commission to study the industrial and commercial problems in which the journals are interested, and to put forward proposals for their solution.

The capital which French medical publications represent has become considerable. As a medium of publicity they receive substantial sums, and the advertisers have begun to collaborate with each other, the better to bargain with the managers of the medical journals. In other words, there are now two fairly well-organised camps whose mutual hostility is tempered by the reflexion that the one could hardly live without the other.

DENTISTS IN CONGRESS

A congress devoted to dentistry and allied subjects has just been held in Paris, and no visitor could have attended it without being impressed with the variety and importance of modern dental activities. Many of the papers indeed might be described as "paradontological"; for example, the subjects included the treatment of tuberculous glands in the neck, the treatment of cancer of the tonsil, and actinomycosis, also dealt with in a special paper. Pyorrhœa aroused keen discussion, and a book on it lately produced by Dr. Roy, of the Ecole Dentaire de Paris, received well-deserved attention.

lowest represent some limited region of the body; the middle are re-representative; the highest are re-re-representative. With the actual sites and physiological activities of these levels we need not here deal; and it is true that in some ways his views on the subject of "levels" were speculative. But the doctrine is what matters; it is finding to-day more assent and substantiation than ever before.

In these and other ways, then, Hughlings Jackson contributed to the science of neurology foundation stones on which others are building—some, doubtless, who know not whence the understructure is derived. Proof of the abiding value of his work has been forthcoming for years now in the increasing attention paid to his views by scholars abroad. His papers and articles (a selection of the more important of which was published in two volumes in 1931–32) take some reading; as Ferrier remarked with truth, there is much repetition and iteration of the dominant ideas, and his style is frequently obscure, owing to the numerous provisos and qualifications which he constantly introduced to prevent his being misunderstood. For these and other reasons they have to be perused at leisure and not at speed; but they contain a wealth of material which has not even yet been fully gone over. It is only when they are thus examined that the knowledgeable reader has been able to find anticipation of later work—a good instance being Jackson's observation of the phenomena of apraxia 30 years before the late Prof. H. Liepmann produced his studies.

Enough has been said to illustrate the reception given by Jackson's colleagues, friends, and scientific contemporaries to his epoch-marking labours, and to support the claim that little indeed of his work "dates"; his enunciation of cardinal principles and elucidation of nervous modes of action do not depend on any manner of thinking that has become obsolete. No doubt Jackson was a product of his period, and in not a few respects advancing knowledge has left him behind; his innate modesty never led him to say more of his views than that they were theories and speculations and that some day he would be "found out"; but he is honoured to-day by neurology the world over, because of his genius in raising ideas of neural activity to higher planes of thought and in discovering unities amid heterogeneous clinical diversities.

MEDICINE AND THE LAW

Mother's Claim to Child

The dispute between Mrs. Hinckes and Mrs. MacLean for the custody of the latter's daughter, Jean Crichton (to which brief allusion has already been made [1]), was settled last week when argument in the Court of Appeal had disclosed a position of some legal difficulty. Jean was born in 1923; when three weeks old she was placed with Mrs. Hinckes, the proprietress of a home for babies. Mrs. MacLean, employed as a nursing sister overseas, was unable to make a home for the child; she paid Mrs. Hinckes £65 a year till August, 1930. Then, after a year's lapse owing to her unemployment, she resumed payments at the rate of £45 a year till 1933, when she returned to England for reasons of ill-health. It was clear that the mother made provision for her daughter's maintenance to the extent of her power. It was also clear that Mrs. Hinckes, having grown fond of the child, was willing to keep her without payment, and indeed wanted to keep her altogether. In 1933, when Jean spent part of her holidays with her mother, Mrs. Hinckes applied to the Steyning magistrates for an adoption order, but the mother refused her consent. This refusal was fatal to the application in view of Section 2 (3) of the Adoption of Children Act, unless the magistrates thought that the mother had deserted the child or persistently refused to contribute to its support or was a person whose consent "in the opinion of the court and in all the circumstances of the case" ought to be dispensed with. Mrs. MacLean wanted the return of Jean and, being now able to make a home for her, took out a writ of *habeas corpus*. As is well known, this procedure is one of the historic safeguards of English freedom. The courts thereby inquire the causes for which any of the King's subjects are deprived of their liberty; it is the pre-eminent remedy for illegal confinement. Its use in the present connexion was a little uncommon, and Mr. Justice Atkinson, before whom the case came, seems in part to have treated the proceedings rather as an application under the Adoption of Children Act than as a question of the grant or refusal of an order of *habeas corpus*. He made a conditional direction for which there seems no precedent. He saw Jean and the two claimants privately, and he learnt that Mrs. Hinckes was willing to apply at present for an interim adoption order only; she was willing to keep Jean for two years at her own expense and would allow Mrs. MacLean to have the child at holiday times. He found that Jean was afraid of, and had no affection for, her mother. He therefore refused to order the return of Jean to her mother forthwith but made a direction substantially in the terms of the interim adoption order for which Mrs. Hinckes was asking. Mrs. MacLean appealed to the Divisional Court, where the two judges took the view of "the man in the street," that a mother ought not lightly to be deprived of her child and that this particular mother could not be a bad guardian for her daughter if the court below had been willing to let her have the child for the holidays. Mrs. Hinckes in turn appealed to the Court of Appeal on the ground that Mr. Justice Atkinson had seen the girl and had consulted her wishes, whereas the Divisional Court had declined to see her and therefore had no material whereon to overrule him. It was argued for Mrs. Hinckes that Jean would have a better home if she stayed where she had been brought up, and that there was no evidence of genuine affection on the part of the mother. At the end of the day Lord Justice Slesser drew attention to the unprecedented and possibly irregular action of Mr. Justice Atkinson in attaching conditions to an order made on a *habeas corpus* application. Next morning the court announced that the case had been wisely settled on terms which were not disclosed. Thus we have no judicial guidance as to the mother's legal right to her child, or as to her right to have an opportunity of winning its affection before custody is finally transferred to someone else.

Fallibility of Identification

The fallibility of human testimony in identifying dead or injured bodies is a phenomenon of which coroners and police officers are well aware. There was a fresh instance at a Bath hospital last week. A motor-cyclist was thrown from his machine and fell under a two-ton lorry, sustaining severe injuries to the head. There was no immediate means of identification when he was brought to the hospital, but, according to the local newspaper, one of the ambulance party suggested that the patient was a Mr. M., vice-chairman of the Bath City Football Club. A porter at the hospital, who knew Mr. M., confirmed the suggestion. A fellow-director of the Football Club happened to be at the hospital and had no hesitation in identifying the injured man as his colleague Mr. M. Someone having communicated with Mr. M.'s household, his father went to the hospital and recognised the patient as his son. It was not till Mr. M.'s wife arrived that the mistake was discovered. She at once declared that the man was not her husband. Later in the day the real Mr. M. came home safe and sound and the true identity of the motor-cyclist was established. Such is the force of suggestion; one person's statement persuades others. If St. George is seen upon the walls of Jerusalem by hundreds of Crusaders, there must be someone who sees him first before the crowd accepts the miracle.

[1] THE LANCET, March 23rd, p. 690.

It must often happen that the law is too easily satisfied with identification by witnesses who may be mistaken. When Adolf Beck was first sentenced some 40 years ago, 15 out of 17 women identified him as the man who had swindled them. When he was convicted again in 1904, 19 women identified him. But when it appeared that a judicial blunder had been committed and that the real criminal was a man named Thomas, who had been arrested on similar charges of swindling, witnesses who had identified Beck now agreed that Thomas was the man. Successful defenders like Serjeant Ballantine and Sir E. Marshall Hall have secured acquittals by producing in court somebody who closely resembled the accused man then undergoing trial; the chief witnesses for the prosecution could not distinguish one man from the other and conviction was impossible. The classical illustration of the fallibility of identification was the Tichborne litigation of the eighteen seventies. Roger Tichborne, the missing heir, had been slight and delicate, with a long narrow face and thin straight dark hair. Arthur Orton, the claimant, weighed 24 stone and had a large round face crowned with a mop of fair and rather wavy hair. A hundred witnesses recognised Orton as Roger Tichborne. The latter's mother was the most persistent in believing the impostor to be her son. Alone of her family, she had refused to believe that Roger was drowned when the ship in which he travelled foundered with all hands. She advertised for news of him, and, when the claimant came forward, she had made up her mind before she saw a line of his handwriting or heard a fact about his history. She recognised him as soon as she saw him first in a hotel bedroom on a dark afternoon in winter, and nothing could shake her faith afterwards. With Lady Tichborne the wish was father to the thought, but cases where all motive or interest is absent are not free from mistake. However fairly an identification parade is conducted at a police station the results must contain an element of uncertainty. Experiments have shown that trained observers, dispassionately doing their best, can err like other human beings.

PARIS

(FROM OUR OWN CORRESPONDENT)

THE FRENCH MEDICAL PRESS

THE recent annual dinner of the Association de la Presse Médicale Française serves to remind the rest of the medical world of the existence of this very live body. Sir Dawson Williams used to call medical journalism the smallest specialty in medicine but the Association is none the less powerful in its own way, and an effective guardian of its members' interests. It began quite modestly half a century ago with the object, convivial rather than trade-unional, of bringing together every quarter the directors and editors of the medical journals. On these occasions solutions were found to problems whose discussion in the press might have been less amicable, since it is easier to agree over a glass of wine than over the printed page. The annual subscriptions covered the cost of the meals eaten, and provincial colleagues were invited to fill gaps left at the table by absentee members. After the late war, however, difficulties arose requiring more than conviviality, and from being an informal dining and debating society the Association has had to convert itself into a *syndicat*, a sort of trade-union, fighting for the interests of its members. With the devaluation of the franc and the rise in the cost of production, the medical journals have had to charge more both to subscribers and advertisers, though considerable economies have been effected by centralised purchase of raw materials and other means. A united front has also had to be shown to the collectors of taxes. The reluctant admission that the scientific and brilliant editor does not necessarily possess all the qualifications required of a successful business manager has led to a certain readjustment between the editorial and managerial departments, to the benefit of both; and here, again, the Association has oiled the wheels of progress. At its last annual meeting it appointed a technical commission to study the industrial and commercial problems in which the journals are interested, and to put forward proposals for their solution.

The capital which French medical publications represent has become considerable. As a medium of publicity they receive substantial sums, and the advertisers have begun to collaborate with each other, the better to bargain with the managers of the medical journals. In other words, there are now two fairly well-organised camps whose mutual hostility is tempered by the reflexion that the one could hardly live without the other.

DENTISTS IN CONGRESS

A congress devoted to dentistry and allied subjects has just been held in Paris, and no visitor could have attended it without being impressed with the variety and importance of modern dental activities. Many of the papers indeed might be described as "paradontological"; for example, the subjects included the treatment of tuberculous glands in the neck, the treatment of cancer of the tonsil, and actinomycosis, also dealt with in a special paper. Pyorrhœa aroused keen discussion, and a book on it lately produced by Dr. Roy, of the Ecole Dentaire de Paris, received well-deserved attention.

FORENSIC SEQUEL TO AN INJECTION OF CAMPHOR

A too legally minded engineer, Michel Hertz, has lately demonstrated the unwisdom of suing your doctor for damages just because something goes wrong. Having undergone resection of the nasal septum, he was three days later given a subaponeurotic injection of oil of camphor into the right thigh. A diffuse phlegmon ensued. The surgeon whose nurse had given the injection was accordingly sued for the modest sum of 100,000 francs. The first medical referee reported in favour of the claimant, arriving at his verdict by what he admitted was a process of exclusion. It seemed to him that, in the absence of other plausible explanations for the genesis of the phlegmon, it behoved him to assume that the nurse had not observed the necessary antiseptic precautions. The surgeon claimed and was allowed another medical opinion, which was given by three experts who, in their lengthy report, came unanimously to the conclusion that the mishap could not be traced to any fault of cleanliness. Although the phlegmon had developed at the site of the injection and was, like it, subaponeurotic, and although there was no question as to the sterility of the injected fluid, it was impossible to exclude the hypothesis of a phlegmon forming as a more or less innocent fixation abscess. In other words, camphor may localise germs which have been circulating in the blood, or may even provoke a sterile abscess. With this possibility always present, it was argued for the defence that the defendant could not be held responsible for the phlegmon in this case, the less so as no direct evidence had been produced as to the non-observance of the proper ritual of a sterile injection. Although the claimant lost his case, being awarded no damages and having to pay the costs of the action, it is to be feared that this legal decision will do little to stem the tide of compensation-thirsty litigants whose numbers are growing yearly.

FUSION OF FRENCH TUBERCULOSIS JOURNALS

For several years the Comité National de Défense contre la Tuberculose has published an excellent journal, the *Revue de Phtisiologie*. Another journal, also excellent, the *Revue de la Tuberculose* has been published by the Société d'Etudes Scientifiques sur la Tuberculose. Their individual merits could not, however, hide the fact that they were overlapping each other, and the fusion of the two is now an accomplished fact. The new monthly journal appears with the title of *Revue de la Tuberculose*, and represents both associations.

A MEMORIAL TO ÉMILE ROUX

Under the patronage of the President of the Republic and many distinguished Frenchmen in all the walks of life, a national subscription has been opened for the creation of a Roux Foundation whose funds are to be devoted to providing scholarships for young students with an aptitude for the biological sciences. It is hoped that the financial resources obtained for this object will enable the Pasteur Institute to continue to promote that research which Roux valued so highly, and which of late has been greatly hampered by the financial losses which the Institute has suffered.

POLAND

(FROM OUR OWN CORRESPONDENT)

RESPONSIBILITY OF A HOSPITAL FOR DAMAGES

In insisting on a new trial of a claim for damages against a hospital, despite the fact that it had been dismissed by two other courts, the Supreme Court has created an important precedent. The plaintiff, who had previously been sound and healthy, received dental treatment at a clinic in 1933. Later an ulcer appeared near the affected tooth and she was found to be suffering from syphilis. It is alleged that the instruments used by the dentist had not been properly cleaned, and that the infection had entered the system by a small lesion near the tooth. The patient claimed heavy damages; she held that she should be compensated, not only for cost of treatment and expenses incidental to her illness, but also for her diminished chances of marriage. The first two courts that heard the case dismissed it on the grounds that a hospital may not interfere with the work of its surgeons, and therefore cannot be held responsible for their mistakes. The Supreme Court, however, distinguished between mistakes due to lack of skill or an error of judgment, and mistakes due to gross negligence which it considered the organisation of the hospital should be able to prevent, and it ordered a fresh trial.

IRELAND

(FROM OUR OWN CORRESPONDENT)

PUBLIC HEALTH IN THE FREE STATE

In introducing his estimate for local government and public health to the Dáil last week, the Minister, Mr. Sean T. O'Kelly, was able to give an encouraging report as to the public health of the country during the year. He stated that there was a distinct improvement in the incidence and death-rate from the principal epidemic diseases. A total of 667 deaths were recorded as due to influenza, as against 1791 in the previous year, and an average of 1438 for five years. The infant mortality had fallen from 65 to 63 per 1000 from the previous year, the average for five years being 69. The maternal mortality-rate was the same as in the previous year—4·4 per 1000 births—but the mortality from puerperal sepsis had increased from 80 deaths to 92. There was a decline in both the incidence of and the mortality from diphtheria. The Minister thought that this improvement might be largely attributed to the immunisation campaign which was being pursued all over the country. Enteric fever had shown a rise from 440 cases in 1933 to 590 in 1934, and the number of deaths had increased by 14.

Medical officers of health had been appointed in 22 counties; 4 counties were proceeding to make appointments; and steps were being taken to compel the remaining county to make an appointment. Schemes for the treatment of tuberculosis were in operation in every area except the county of Longford, and a scheme would soon come into force in that county. There had been no addition during the year to the districts in which school medical inspection schemes were in operation—namely, 4 county boroughs and 18 counties. The appointment of more county medical officers of health would make possible an extension of school schemes.

THE MILK BILL

The Milk and Dairies Bill, 1934, passed its final stages in the Dáil last week, and is now before the Senate. The Bill makes provision for the registration of all dairies and dairymen engaged in the sale of milk, the registration to be in the hands of the local health authorities. The local authority is given the right of entry and inspection. In certain conditions the medical officer of the local authority is given the power to examine the person of workers in dairies suspected of being the source of infection in milk. The Minister is authorised to make regulations prescribing the designations under which milk may be sold or offered for sale, and to issue licences for the use of such designations. It is prohibited to use such a designation without a licence. Strict provisions are intended to prevent the sale of infected milk and the sale of milk from diseased animals. Adequate powers are given to the local authority for the sampling and bacteriological examination of milk offered for sale.

It may be said that the Bill furnishes a not unsatisfactory code of law for the control of milk in the hands of an energetic local authority. Its whole success in practice will depend on vigour in administration. Unfortunately a public health system is of such recent birth in Ireland that the people of the country and the members of the local authorities are alike unaccustomed to active public health administration. Most of the county medical officers, themselves only recently appointed, have their hands full already with other duties, and unless given adequate assistance can hardly spare much time to the administration of the present measure. The interest of the local authorities will be considerably chilled by the fact that the entire expense of working the Bill is thrown on their shoulders. The Government would have got much more ready coöperation from the local authorities if the expense of administration had been divided between local and central funds. In some minor matters the Bill is capable of amendment, and it is hoped that the Senate may succeed in getting some improvements made.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

MENTAL DISEASE IN SCOTLAND.

THE steady accumulation of certified patients in mental institutions continues to present a serious problem. According to the General Board of Control for Scotland, whose 1934 report has now been issued, there were in Scotland on Jan. 1st of this year 19,685 insane persons of whom the Board had official cognisance. This represents an increase of 147 compared with the previous year. All the asylums have exceeded the number of patients which can be accommodated with safety from the point of view of health and administration, and many have become gravely overcrowded. The system of boarding-out in Scotland has been attended with conspicuous success, and the Board advise that the use of this method should be accelerated. This would help to relieve congestion, but extension of asylum accommodation is also urgently required. The death-rate of patients in mental hospitals, per cent. of the average number resident for the year 1934, was 6·9.

There is a steady lessening of public prejudice against mental hospitals, and with this change the difficulty of accommodation is bound to become more and more acute. There is, for example, an increasing tendency to send elderly patients with cerebral degeneration, due to vascular disease or tumour, to mental hospitals, owing to the difficulty of handling such cases at home or in a general hospital. General hospitals are intolerant of patients with mental confusion, aphasia and incontinence, but it sometimes seems to be a little cruel to certify elderly patients suffering from organic disease of the brain such as cerebral tumour and cerebral thrombosis.

THE LATE COLONEL THOM

The sudden death of the superintendent of Edinburgh Royal Infirmary will be felt keenly by the managers and by all who work in the hospital. Colonel Thom had a remarkable gift for organisation and for seeing that everything was done properly. He spared himself no effort to improve the efficiency of the Infirmary, and by his enthusiasm, tact, and kindliness, not only enlisted the whole-hearted coöperation of the staff, but at the same time won their deep affection and regard. It is no easy matter to superintend a voluntary hospital of 1000 beds, and it is still harder to appreciate the traditions and peculiarities which such a hospital possesses. Colonel Thom, however, very soon grasped the situation with such ability that both the managers and members of the staff came to count on his advice when difficulties arose. His charming personality made it a pleasure to discuss difficulties with him, and his death gives us at the Infirmary a feeling of personal loss; the R.I.E. will not be the same without "the Colonel."

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 30TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2519; diphtheria, 1372; enteric fever, 16; acute pneumonia (primary or influenzal), 1799; puerperal fever, 41; puerperal pyrexia, 145; cerebrospinal fever, 33; acute poliomyelitis, 4; encephalitis lethargica, 6; continued fever, 1 (Ebbw Vale); dysentery, 7; ophthalmia neonatorum, 104. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 6th was 3885, which included: Scarlet fever, 1144; diphtheria, 1716; measles, 22; whooping-cough, 348; puerperal fever, 23 mothers (plus 10 babies); encephalitis lethargica, 270; poliomyelitis, 2. At St. Margaret's Hospital there were 19 babies (plus 12 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London there was no death from small-pox, 3 (1) from enteric fever, 20 (0) from measles, 6 (0) from scarlet fever, 27 (5) from whooping-cough, 47 (6) from diphtheria, 48 (14) from diarrhœa and enteritis under two years, and 181 (26) from influenza. The figures in parentheses are those for London itself.

The peak of influenzal deaths has probably been reached, the number of reported deaths for the last few weeks, working backwards, being 181, 175, 145, 139, 83, 91, 83, 91, 71, 56. This week these deaths were reported from 69 great towns; Liverpool reporting 12, Manchester and Birmingham each 11, Sheffield and Sunderland each 7, Stoke-on-Trent 6, Oldham and Bristol each 4. (During the same week Glasgow reported 33 deaths, Edinburgh 8.) Wolverhampton reported 3 fatal cases of measles, no other town more than 2. Three deaths from diphtheria occurred at Bradford, at Leeds, and at Newcastle-upon-Tyne.

The number of stillbirths notified during the week was 288 (corresponding to a rate of 43 per 1000 total births), including 48 in London.

NEW HOSPITAL AT EAST GRINSTEAD.—The market town of East Grinstead, in Sussex, with its rapidly growing community, has long been confronted with the need of a larger hospital. In 1929 a scheme was brought before the townspeople, but little support for it was forthcoming; it was thought that the time was not ripe for an outlay of £25,000, the figure then mentioned. Rapid building developments in the town and the surrounding district quickly increased the demand for beds at the existing Queen Victoria Hospital, with the result that the 12 beds, 3 cots, and 1 paying ward were constantly occupied, and cases had to be sent to London, Redhill, Tunbridge Wells, and Haywards Heath. This created an outcry, and in 1931 a public meeting of 400 residents voted unanimously for a new hospital. The building, whose foundation-stone was laid by Lord Horder on April 6th, will cost £27,000, and of this sum only £4500 remains to be raised. In a short speech Lord Horder spoke of the sound principle of decentralisation of hospital work. The dissemination of medical and surgical advances was now so rapid, he said, that they knew nearly as much in East Grinstead as in London. Moreover, there were advantages in treating and nursing patients in the country rather than in London, and he could not call to mind a cottage hospital so well situated and so admirably conceived as that at East Grinstead. Lord Horder went on to say that he was still an advocate of the voluntary hospital system, and he hoped that any change towards another system of administration would be a gradual one.

PUBLIC HEALTH

Hospital Services in Scotland

In contrast to the position in England and Wales, where the power of local authorities, including county councils, to provide hospital accommodation of any kind is absolute under the Public Health and Local Government Acts, in Scotland it is limited to the councils of counties and large towns (over 20,000 in population) and is contingent upon approval by the Scottish Department of Health of considered schemes for the reorganisation of the hospital facilities of these councils. South of the Border, it is true, a council proposing to make new hospital provision must consult a body representative of the voluntary hospitals in the area, but there is nothing to compel it to adopt the latter's suggestions. If it intends to borrow for the purpose, as is usually the case, the Minister's sanction must be obtained so that, indirectly, the Ministry of Health is able to signify its approval or disapproval of the scheme. In Scotland, however, the central department's duty to review the whole of the institutional provision in an area, whether under council or voluntary management, before signifying approval of a scheme, is obligatory under Section 27 of the Local Government (Scotland) Act, 1929. The Scottish department must, therefore, review all the hospital accommodation available for the people of an area when any proposal for increasing or reorganising it is made; and it must be satisfied that the authority has taken reasonable steps to seek and continue to secure full coöperation with every voluntary hospital, university, or medical school within *or serving* the area.

FIVE REGIONAL CENTRES

It will be seen that this duty really places the department in a position to exercise the initiative in hospital reorganisation and it has set out a very definite policy as to how the Act of 1929 should be made effective. The great teaching centres of Edinburgh, Glasgow, Aberdeen, and Dundee have all along served a much wider area than these towns through their associated hospitals, and it is proposed that these should form regional centres, a fifth region, comprising a large part of the Highlands, being centred on Inverness. The department has set its face against the multiplication of small and inefficient units. Its aim is set out thus [1]:—

> (1) to raise the standard of institutional treatment of the sick poor to the accepted general hospital standard;
>
> (2) to secure, by coöperation—in any of its numerous forms—between local authorities of adjacent areas the maximum development of a few chosen institutions rather than the uncoördinated extension or indefinite continuance of a large number of small units, more or less duplicating one another's services, equipment, and staffs;
>
> (3) to foster coöperation between the statutory and the voluntary hospital authorities so that together they may make a full contribution to the treatment of the sick, to medical teaching and research, and collaborate in the solution of those problems of hospital administration (e.g., allocation of patients, scales of charges and payments of staffs) in which their interests are, or must ultimately be, inextricably intertwined.

Even before the transfer of poor-law functions, a measure of coöperation between districts had been attained, some use had been made of poor-law hospitals for medical education, and the city and county councils of Aberdeen had gone far in attaining a common hospital policy, in collaboration with the voluntary hospitals serving their areas. Obviously it will take a long time to make the proposed regional system really effective. Practitioners in remote parts will incline to send their difficult cases to the teaching hospitals where they were trained, in preference to a centre which, perhaps, they have never seen, and with the staff of which they have had no contact. At first sight it would appear that the inclusion of Argyll, parts of which are close to and within easy access of Glasgow, in a region centred upon Inverness is irrational, but, no doubt, the department is faced with the need for increasing the population served at this centre in the interests of efficiency, and it may be that it expects difficulties of distance and transport to be overcome by the development of the air ambulance service already established by Argyll county council and other Highland authorities.

COUNCIL OR POOR LAW

As in England and Wales, the council hospitals exceed the voluntary hospitals in number and accommodation. There are 243 council hospitals, with 18,670 beds, as against 206 voluntary hospitals, with 12,575 beds. When, however, special hospitals of the kind which serve those purposes which have long been the province of statutory public health administration are deducted (e.g., hospitals for fevers, tuberculosis, maternity, and children's diseases) there are left, under local authorities, 59 poor-law general hospitals, with 5570 beds (of which 55, with 3270 beds, are mixed institutions, in Scotland called poorhouses), and 5 general hospitals, transferred away from the Poor Law, containing 1580 beds. The total number of general hospital beds under local authorities is therefore 7150, compared with about 7000 voluntary beds allocated to general surgical and medical work. The department draws attention to the inferior structure and inadequate staffing of most of the 55 mixed poorhouses, and the bad tradition which hinders their development. Nothing short of the removal of the sick from these institutions to proper hospitals will, in its opinion, enable the ideals underlying the Act of 1929 to be achieved. It should be one of the first aims of local health administration. The retention under the Poor Law of some of the largest and most up to date of the transferred hospitals, such as those in Glasgow, is a matter for some surprise, but it must be remembered that the Scottish Local Government Act contained a saving clause in Section 12, enabling a council to transfer administration of an institution to another committee than the public assistance committee "for the purpose of coördinating the services provided by the council," an action which could not be taken in England and Wales without the formality of appropriation. In effect, therefore, it is possible in Scotland to substitute the spirit of public health administration for that of the Poor Law, while leaving the selection and admission of patients under the old régime. It is a compromise, however, which should be temporary and is bound to hinder that full coöperation with the voluntary hospitals and medical schools which the department desires.

LOCAL OBSTACLES

While some progress in hospital reorganisation is recorded in 1934, the department is meeting with obstacles of local interest, prejudice, and inertia for which, no doubt, they were prepared. An attempt to centralise accommodation for infectious diseases in Ayrshire has failed because of disagreement as to methods between the county and Kilmarnock town councils. An effort to persuade Dunfermline town council to look far ahead in its planning of new maternity beds, so that they should ultimately form part of a hospital centre, was only partially successful. The town council of Stirling seems to be determined upon the improvement of its own small fever hospital rather than coöperation with the county council. In spite of more enlightened movements in Inverness and Fife, the department records that progress in hospital reorganisation has been slow and, on the whole, disappointing.

---

[1] Sixth Annual Report of the Department of Health for Scotland, 1934. H.M. Stationery Office. 3s. 6d.

APPOINTMENT OF A DIETITIAN AT HAMMERSMITH HOSPITAL.—Among the special cases concentrated at Hammersmith Hospital will be many requiring special dietetic treatment, and a special dietetic kitchen is being arranged, to be ready for use, if possible, by July 1st. All the L.C.C. hospitals have food supervisors in charge of the ordinary kitchens, but it is proposed to put a dietician in charge of this kitchen at a salary of £150–£10–£200, together with board, lodging, washing, and uniform.

L.C.C. AND I.C.A.A.—The London County Council having been informed by the Invalid Children's Aid Association that its provision of convalescent treatment for children referred to it by hospitals, care committees, and the like, is likely to be curtailed by lack of funds, the Council proposes to use the services of the Association for the disposal of children for whom the Council is itself unable to provide. Capitation payment will be made at the rate of 7*s.* 6*d.* a week for eight weeks, and the situation will be reviewed in six months' time.

PANEL AND CONTRACT PRACTICE

A National Laboratory Service

IN the teaching hospitals the medical student is called upon to devote a large part of his time to laboratory work, both practical and theoretical, but so far as the medical man going into panel practice is concerned, this part of his training is largely nugatory, for the National Health Insurance Acts make no provision whatsoever for any form of laboratory service for patients insured under the Acts. The insurance practitioner may prescribe what he likes in the way of drugs, proprietary or otherwise, but he is given no facilities for ascertaining in the first instance whether his diagnosis be correct, and in the second the response of his patient to the treatment given. Sir Ernest Graham-Little recently asked the Minister of Health if provision could not be made at an early date for such a laboratory service, but the Minister held out no hope of any immediate extension of the scope of medical benefit in this direction. A memorandum issued by the Association of Clinical Pathologists points out that in certain districts, e.g., Manchester and Wigan, local arrangements have been made, rendered possible by loop-holes in the Acts, and for the reason that unallocated funds happened to be available. In other areas, e.g., Chester and Wolverhampton, laboratory facilities have been offered by the local voluntary general hospitals at special cheap rates. The Association holds the view that a matter of this importance should be dealt with otherwise than by taking advantage of loop-holes in Acts of Parliament or by the charity of voluntary hospitals, and for some years past it has been urging the inclusion of laboratory examinations as a benefit under the National Health Insurance Acts. A schedule of charges has been drawn up at which the investigations essential in general medicine can be performed without loss to the laboratories performing them. The Association is of the opinion that clinical pathology can only be properly carried out by those in close touch with clinical medicine, that is to say, in the laboratories attached to general hospitals. There exists to-day a network of such laboratories conveniently distributed over England and Wales in all the more important towns; with their aid the pathological services needed by insured patients could readily be met.

The Practitioners' Fund for 1934

The amount of the fund has been finally determined by the Ministry of Health at £6,676,573. This amount is subject to economy deductions, 10 per cent. for the first half year, and 5 per cent. for the second, the amount available for distribution being £6,175,830. Insurance practitioners therefore contributed from their remuneration in 1934 over half a million pounds towards placing the country on a sound financial basis. It is to be hoped that the Chancellor of the Exchequer, in view of his Budget surplus, may be able to restore the capitation fee to its normal value during the present year.

London's share of the fund continues to decrease. In 1933 the areal percentage was 12·6666, but for 1934 it was 12·5685, producing £776,209. Of this amount £762,645 10*s.* had been distributed by way of quarterly advances; so that including a balance of £1 7*s.* 11*d.* brought forward from 1933 there remains £13,564 to be distributed, as compared with £18,892 last year. The total payment for 1934 will amount to 8*s.* 7·4932*d.* per unit of credit, as compared with 7*s.* 11·4652*d.* for 1933. Some of this increase is, of course, due to the remission as from July 1st of half the economy deduction, but the clearance of the medical register which took effect as from Jan. 1st, 1934, made a difference of nearly sixpence in the value of the unit of credit in London.

The amount of the fund for 1935 has been provisionally determined, after deduction of 5 per cent., at £6,050,000, and, as in previous years, the Ministry state that it must not be assumed that the final determination of the fund will necessarily enable any additional payment to be made to practitioners at a later date.

What is a Partnership?

This question sometimes becomes a conundrum. It was related in this column on Feb. 2nd that Dr. A. and Dr. B., having between them a list of some 5000 insured persons, were said to be in partnership. Dr. B. left the practice and Dr. C. joined Dr. A. as a partner, signing the necessary form, in which it was declared that Dr. C.'s share of the profits was not less than one-third of Dr. A.'s. Information having been received about the terms of the agreement between Dr. A. and Dr. B., the committee refused to recognise Dr. C. as a partner until the partnership deed had been produced for inspection. The committee's solicitors held that Dr. C. was not in the position of a principal and that his share of the profits was obviously less than a third of Dr. A.'s share. The insurance committee agreed with the legal opinion, and it was expected that the firm would be surcharged for the 1000 patients or so exceeding the maximum permitted to principal and assistant. The practitioners having been informed of this decision, their solicitors wrote contesting it but expressing the willingness of Drs. A. and C. to consider any change in the partnership deed which the committee's legal advisers might suggest as desirable.

A conference between the solicitors for the two sides has been arranged, but meanwhile the question arises as to the basis upon which payment should be made for the quarter commencing Jan. 1st, 1935. The allocation scheme lays it down that a practitioner shall be given a period of two months from the date upon which an excess number of insured persons on his list was discovered within which to make arrangements to bring his list into conformity with the scheme. The areal distribution scheme (which in this respect differs from the model distribution scheme) provides that for the purposes of the distribution of the practitioners' fund the number on the list of a practitioner shall not in any case be deemed to exceed 2500 in the case of a practitioner practising otherwise than in partnership. . . The effect of the committee's decision of Jan. 24th is to place Dr. A. in the position of a practitioner practising otherwise than in partnership, but it appears that by the terms of the allocation scheme (which would seem to be somewhat in conflict with the distribution scheme) he has a period of grace of two months as from Jan. 24th within which to make arrangements for carrying out the requirements of the regulations. Payment to Dr. A. and Dr. C. for the current quarter will accordingly be based upon their actual figures of credit.

A Revised Scheme at Newcastle-upon-Tyne

On April 3rd the city council of Newcastle-upon-Tyne adopted a revised scheme of payment for the medical practitioners working the open-choice method of providing domiciliary medical services in the city. The position was set out in this column a fortnight ago. Instead of participating in a fixed pool of £1200, which was the amount provided for the six districts concerned, the scale of remuneration will now be as follows :—

(1) 20*s*. per annum for patients receiving medical treatment throughout a period of 12 months ;

(2) 5*s*. per quarter for short-period cases ;

(3) special fees payable for confinements, fractures, certificates, &c., to remain as at present.

The scheme is to be tried out for the year beginning April 1st, 1935 ; payment on the same scale will be made retrospective to Nov. 8th, 1934. It is anticipated that the new scale of remuneration will produce 1*s*. 3¼*d*. per unit service as contrasted with 5½*d*. under the pooling arrangements. The original scheme applied to six of the ten medical relief districts in the city. A seventh district has now been added. The estimated cost of domiciliary medical services, exclusive of drugs and dressings, is estimated at £3485 a year.

An Urgent Night Call

An insured person attended at a practitioner's surgery on an evening when he was away and a locum tenens in charge. She declined his offer to open a whitlow under an anæsthetic, but undertook to apply hot fomentations at home, it being understood that she would call at the surgery on the following morning. During the night pain became intense, and at about 4.30 A.M. application was made by her sister and a friend at the practitioner's residence for an immediate visit as the insured person had fainted. The messengers were informed by the practitioner's mother that he was out, and they intimated that, in the circumstances, they would have to obtain the services of another doctor. This they did and incurred thereby expenses amounting to half a guinea. The London insurance committee, in considering the question of responsibility for this fee, elicited the fact that the practitioner's mother was acting under his direction when she informed the messengers that he was not at home, although as a matter of fact he was standing on the stairs listening to the conversation. There was some divergence of testimony as to whether the patient's name was mentioned—she lived at a house which is also occupied by other families—but it was clear that no application was made in terms for a visit to an insured person. The practitioner stated that although he would not have responded to a call from a private patient, he would have responded if he had understood that the application for his services was in respect of one of his insured patients. The medical service subcommittee in its report states that it is, of course, desirable that an insured person applying for treatment, or a messenger applying on behalf of an insured person, should indicate to the practitioner that treatment is required for an insured person ; and if the practitioner has any reasonable doubt about the identity of the applicant, he is entitled to require the production of the medical card. But in this case it was felt that the messengers having been informed that the practitioner was out, their view that in his absence the question whether the patient was insured or not did not arise was perfectly reasonable. Having regard to the hour and the emergency, the failure on the part of the applicants to indicate that the practitioner's services were required for an insured person seemed to the committee of secondary importance in view of the incorrect information given to them by the practitioner's mother. The subcommittee found that the practitioner had committed a breach of the terms of service in failing to provide treatment to an insured person who had applied to him ; and that expenses amounting to 10*s*. 6*d*. were reasonably and necessarily incurred in obtaining the services of another practitioner. The insurance committee adopted the subcommittee's recommendation that the practitioner should be required to accept responsibility for the payment of the fee to the other doctor.

Police Convalescent Home at Hove.—No fewer than 1016 police officers were received by the Police Convalescent Home at Hove last year. Of these London supplied the large majority, and at the annual meeting on March 18th Mr. Max Page, consulting surgeon to the Metropolitan Police, stated that during the ten years he had been sending men to the Home they had always returned absolutely sane in body and mind. Unfortunately the financial position is causing some concern, for the credit balance amounts to only a few pounds. In the absence of the Home Secretary, Sir John Gilmour, the proceedings were presided over by Mr. Norman Kendal, assistant commissioner to the Metropolitan Police. Lady Gilmour represented her husband. Warm tribute was paid to the hon. medical staff, Dr. E. Wight, and Dr. C. Curwen ; also to Miss M. Kerr, hon. lady superintendent.

Fellowship of Medicine and Post-Graduate Medical Association.—An afternoon course in psychological medicine will be given at the Maudsley Hospital from April 23rd to May 31st. Other forthcoming courses include dermatology at the St. John's Hospital (April 29th to June 1st); medicine, surgery, and gynæcology at the Royal Waterloo Hospital (April 29th to May 11th); thoracic surgery at the Brompton Hospital (May 13th to 18th); chest diseases at the Brompton Hospital (two afternoons a week at 5 P.M., in June); chest and heart diseases at the Victoria Park Hospital (two afternoons a week, at 6 P.M., in June); evening clinical and pathological class (two evenings a week in June). Week-end courses include cardiology at the Victoria Park Hospital (May 4th and 5th); chest diseases at the Brompton Hospital (May 11th and 12th); and fevers at the Park Hospital (June 15th and 16th). Courses of instruction and clinics arranged by the fellowship are open only to members and associates, with the exception of the course at St. John's Hospital.

PARLIAMENTARY INTELLIGENCE

OSTEOPATHS BILL

Select Committee's Inquiry

(Continued from p. 836)

THE *Committee's inquiry continued on Friday,* April 5th and Monday, the 8th, with Lord AMULREE in the chair.

Presentation of the Book

At the outset Mr. THORPE, K.C., principal counsel for the promoters, presented to the members of the Committee copies of a book entitled "The Scientific Basis of Osteopathy." The book, he said, had been written by Dr. Kelman Macdonald in the last eight days, and set out, so far as had been possible in the time available, the justification for osteopathy.

Sir W. JOWITT, K.C., principal counsel for the British Medical Association, said that he did not object to the presentation of this book, though it was a rather odd procedure. He had the honour of being referred to in the book, which apparently contained criticisms of what he had said. The book had taken eight days to write, but how long it would take to read intelligibly he did not pretend to say.

Mr. THORPE explained that the book had been largely inspired by Lord Dawson's invitation to Dr. Macdonald to produce any scientific basis for osteopathy which was available. If there was anything in the book on which Sir W. Jowitt would like to ask questions he would ask permission for Dr. Macdonald to be recalled.

Lord DAWSON said he had asked that the original papers already published should be produced.—Mr. THORPE said that they were reproduced word for word in the book.

Lord DAWSON suggested that the book was really a reprint of the 18 research bulletins, plus extra information.—Mr. THORPE agreed. I understand, he said, that the bulletins are there in toto.

Sir Morton Smart's Evidence

Sir Morton Smart, M.D., late medical officer in charge of the electrical department of the Hospital for Sick Children, Great Ormond-street, was called in opposition to the Bill. In answer to questions by Mr. DICKENS, counsel for the British Medical Association, the witness said that since 1896 he had devoted his chief attention and study to manipulative surgery and medicine in all its branches. He had written a text-book and articles on the subject, and had done a great deal of practice in manipulative surgery, particularly in the case of traumatic damage to bones and so on. His view was that manipulative surgery was a valuable method of treatment in certain cases. Those who undertook it should understand the scientific basis on which it depended, and have a knowledge of anatomy, physiology, normal joint action and movement, and pathological conditions. This method of treatment must be preceded by clinical diagnosis. While it was of great value in certain cases, it could in others do great harm. Commonly it was employed in association with, or as a preliminary to, other treatment. The value of such treatment was widely recognised by the medical profession, but it should *not* be applied indiscriminately and unscientifically. He had studied osteopathic literature both in this country and the United States of America, for many years, and he had visited that country several times.

THEORY AND PRACTICE

COUNSEL: You know what the theory of osteopathy is?—WITNESS: Yes.

Are you a believer in the theory of osteopathy?—No.

Have you attempted to understand all the matter which has been put before the public and the profession by the osteopaths?—Yes.

Have you found any evidence of any scientific basis for the theory which the osteopaths hold?—Not for the theory.

From what you know of the theory should it be capable of scientific proof, if it were true?—I think if the theory were true, in view of the large number of people in the world suffering from diseases and disabilities, it would be impossible not to prove it.

Would you go further in regard to the claims in regard to acute disease and say that the untruth of the theory of osteopathy is demonstrable?—Yes.

You would say that it could clearly be demonstrated that their claim for instance in the case of infectious disease is without foundation?—Yes.

Is osteopathy in practice valuable in certain cases?—Yes.

Can you say the extent of its value—it is not of universal value?—Osteopathy—and when I say osteopathy I am referring to manipulative surgery—is definitely useful in a large number of cases. And in the cases in which it is useful it can be shown that the reason is that it is based on well-known pathological knowledge.

The theory of osteopathy has grown considerably since the days of Dr. Still?—Yes.

And have osteopaths apparently been more and more ready to adopt other such therapeutic agents as the medical profession use?—There is overwhelming evidence, both in America and in this country, that osteopaths, while trying to adhere to the original theory of Still have wandered far from that theory and now embrace practically every method of treatment known to scientific medicine.

What do you deduce from that as to the value of the original theory?—I deduce from that that the osteopaths themselves have realised that the original theory cannot possibly be the cause of all diseases and therefore in the name of osteopathy they have taken over every method they could lay their hands on to get results.

Replying to further questions by counsel as to how, in his opinion, osteopaths should be employed, and whether he thought they should be given complete charge of a case from the beginning to the end, the witness said he thought definitely that osteopaths should work under the direction of a medical practitioner who had studied the question. It appeared to him that if any body of practitioners were to be legally allowed to treat the sick, whatever their treatment might be, they should pass a minimum standard similar to that of the medical colleges.

THE VALUE OF PUBLIC DEMAND

In answer to a question by counsel as to the value which he placed on any public demand in these matters the witness said that he thought that the public did not inquire carefully enough into these matters. Most people were liable to think that a treatment was a good treatment because they knew of a case which had been successful while under that treatment; but they did not go closely into the question as to whether it was cause and effect. There were hundreds of examples of that, and the point about the vox populi was that though it might be stated that the public wanted osteopathy, and that might be true, the section of the public who wanted this treatment was far smaller than the public themselves believed. He contended that it was the people who had gone to osteopaths and had been successfully treated who were mainly those who were called the vox populi. On the other hand, there were a large number who had gone to osteopaths and had not been successfully treated.

Lord ELIBANK asked if that would not also apply to doctors. Was that an argument against osteopathy?—WITNESS: Decidedly. It bears out my point that it is not due to successes that a treatment is scientifically assigned.

Lord DAWSON suggested that the point was this, that it was not good evidence for the establishment of any treatment to bring forward a series of isolated cases, and that if they wanted to prove that a particular treatment was successful or not, that could only be done along the lines of scientific methods by marshalling say 500 or a 1000 cases. That applied to any treatment.

Lord ELIBANK asked the witness whether he would say that the cures in osteopathic cases had only been in isolated cases.—WITNESS said he decidedly agreed that the cures by osteopathic treatment were isolated. It was only a certain type of case that was cured by that treatment.

COUNSEL was proceeding to ask further questions on the attitude of the public towards osteopathy when the Chairman interposed.

COINCIDENT CURE

The witness, continuing, said that in his experience over many years he had been up against this question of explaining to patients why certain treatments which they received did not cure them. If osteopathy or other treatment took place pari passu with symptoms from whatever cause, the patient spoke enthusiastically of its success. The coincident cure in spite of treatment embraced an enormous number of apparent successes. A good example was what was called water on the knee. In a great majority of cases such condition, as far as the presence of fluid was concerned, would clear up in from six to ten days, even if no special treatment was prescribed. If such a patient underwent osteopathic treatment and recovered, it was little wonder that such a patient believed that the diagnosis was right when the fluid which was the main symptom, disappeared. The patient believed that it was the direct result of the manipulation of the spine, and naturally as a result the osteopath gained a convert. There was indisputable evidence that harm had been caused by osteopathic manipulation. Particularly was that the case in regard to the wasting of valuable time in critical cases where the diagnosis had been wrong, and where early diagnosis would have effected a cure or would even have saved the patient's life. There were also serious psychological dangers. There had been a large number of cases where osteopathic manipulation had resulted in damage to the soft structures such as the muscles.

The witness went on to quote from McConnell and Teall's text-book, where it was stated that the general rules laid down were applicable to all dislocations, whether partial or complete, and it was further stated that the practitioner should exaggerate or increase the dislocation. The witness, commenting on this, said that if they were dealing with the dislocation of the spinal vertebræ, and one started by exaggerating it, the danger was something appalling. The damage to the cord would be terrible. If anyone was trying to deal with a spinal dislocation, the first essential was not to exaggerate it because of the damage of further pressure on the cord. With regard to the danger arising from the waste of valuable time in such cases, the witness said that it was well known that many cases of tumour of the brain had been treated by osteopaths for a period, and if that period had not been wasted an operation would have given a very great chance of success. He knew of two cases in his own experience of that kind.

COUNSEL: That emphasises the value of proper diagnosis before any treatment is attempted.—WITNESS: Yes.

Turning to the phychological effect on the patient, the witness said that some patients went to an osteopath and had a diagnosis made. For instance, they were told that their hip was out, or their pelvis was out, and that various parts of their spine were out. That had a very serious effect on the patient because it put into his mind that these things were wrong. There had been an actual case of a girl who was going to be married. She had a hip which was bigger on one side than on the other as a result of starting riding side-saddle at an early age. Her future mother-in-law took her to an osteopath, who told her that her pelvis was contracted and small; and that it would be very dangerous if she had any children. The result of that was very serious to the mother and the daughter. He (the witness) pointed out that the best way to decide that was to have the girl X rayed, and it proved that there was no contraction of the pelvis at all.

Lord ESHER: Was that a qualified osteopath.—WITNESS: What is a qualified osteopath? He was not a doctor.

THE QUESTION OF REGISTRATION

On the question as to whether osteopaths should be placed on a State register, the witness said in his view it was not in the public interest that State recognition should be given to a group of practitioners who based their practice on a theory which was unsound and unscientific. If the present Bill was passed it meant that in the opinion of those responsible for its passing the foundations of the principles of osteopathy were admitted to be proved, in spite of the fact of the overwhelming evidence that the medical profession of the entire world disagreed upon these essential points, and the natural corollary was that medical and surgical treatment as practised to-day in all civilised countries, should be prohibited in the public interest. If State registration was to be given to osteopaths on the ground of public demand it would be impossible to decline registration to every other cult—chiropractors, nature curers, Christian Scientists, and so forth—who could prove popularity among the public. The witness added that he would say that such people commanded as much public support as the osteopaths.

In regard to qualifications, the witness said he thought it would be intolerable that those who held diplomas of the British School of Osteopathy should be placed on a State register. No college should be recognised for the purpose of a British State register, the standard of which could not be carefully scrutinised and controlled. It would be absurd to recognise for admission to an Osteopathic register qualifications of a lower standard to those of American medical degrees. He did not think it would be a good thing to have powerful American influence in deciding the standards for admission to a British register.

COUNSEL: Is your opposition dictated by any fear of the consequences to yourself and your fellow practitioners?—WITNESS: Many accusations have been made against the powers that be in medicine in regard to their opposition to the Osteopaths Bill, and none has been more constantly reiterated than that which affirms that we resist the registration of osteopaths because of a fear of the competition which would follow the giving of a legal status. Nothing could be further from the truth than that. That aspect of the matter has never even been considered; Whatever may be the sins of medicine in the past, modern medicine is eagerly ready to receive with sympathy any improvement in technique and treatment, any new ideas in pathology, provided that they are scientifically proved, although it may do so with slowness and caution.

Sir Morton Cross-examined

In reply to Mr. THORPE, the witness said that Dr. Mennell and himself could both fairly be regarded as exponents of manipulative surgery. He was certainly in agreement with some of Dr. Mennell's views, though he did not say all.

COUNSEL: As far as practice is concerned, there is very little difference, if any, between the practice of osteopaths and the practice of manipulative surgeons?—WITNESS: I do not see any reason why an osteopath, or any person accustomed to the manipulation of joints, should not do the actual practice of manipulation as well as any other person.

There is the theory and the practice of osteopathy. As far as practice is concerned are you not doing the same as Dr. Macdonald or Mr. Streeter?—Certainly, as regards Dr. Macdonald.

What is a qualified osteopath?—I should say Dr. Macdonald.

You would not regard any osteopath as qualified coming from an American school?—The Americans themselves do not, and I should not.

Unless a man is a qualified medical man first and then an osteopath you would not call him a qualified osteopath?—No.

Do you object to these unqualified people practising?—Certainly not.

Does it amount to this, that you object to any theory and practice in a man who has not taken a medical degree, and that objection disappears as soon as he takes a medical degree?—Not by any means; it is a question of his skill.

The witness added that he disagreed with Dr. Macdonald in regard to the acceptance of the theory of osteopathy. Replying to further questions, he said he gave drugs where necessary, but in most cases where it was essential to use drugs he would hand the case on to a different type of practitioner to himself. But he was not against the use of drugs.

COUNSEL: But you are not a great believer in drugs?—WITNESS: To a certain extent that is true.

COUNSEL suggested that manipulative surgery was comparatively new in England.—WITNESS: It goes back 400 years before Christ.

How many schools are teaching it?—I think practically all the medical schools have now an orthopædic department.

If the situation remained as it was to-day, the right solution, Sir Morton said, was that osteopaths should act under a qualified medical man, but the better solution would be that osteopaths should take a medical qualification first and then practise osteopathy afterwards.

COUNSEL: You would approve if a medical man called in an osteopath and they worked in conjunction?—WITNESS: For treatment.

The doctor would diagnose and ask the osteopath to treat the patient?—Yes.

That is as far as you go?—Yes.

Sir Morton Re-examined

Replying further to Sir W. JOWITT, the witness explained the sort of case in which manipulative surgery is necessary and effective. The main type of case, he said, was that in which there was limitation of joint movement, usually due to adhesions. There was a second class of case in which the tissue, which was an important part of structures, lost its resiliency and affected the movement of the joint. There were also cases of dislocation—e.g., of the cartilage of the knee, &c. In the correct type of case, he said, manipulation was the only useful treatment.

COUNSEL: Do you think you can do any good to a person suffering from measles?—WITNESS: No; I think it is fantastic.

Or pneumonia?—Equally.

If the osteopathic theory is right can you conceive any room left for the use of drugs?—None.

Can you doubt that there are cases in which the use of drugs is necessary?—Most decidedly. I get many cases where I consider it is essential to consult with other doctors because they are outside my line.

I suppose that manipulative surgery requires a great deal of practice to get your hands good, to use a *riding* phrase. You need good hands and an acute sense of touch, and unless you practice very carefully you cannot do it?—I think it is like everything else where you have a coördinated movement. You have some people who are good at it and some who are not so good at it.

You get a large number of patients sent to you by ordinary practitioners?—Yes.

Have you any doubt that to-day the value of manipulative treatment is fully recognised by the medical profession?—Most decidedly it is—since the war. That was the time when it first came into prominent use. As the result of the war there were many cases which were suitable for manipulative surgery and Sir Robert Jones made a great effort at the time. From that day onwards manipulative surgery has increased unbelievably.

Not long ago we had the Grand National, and I think that no fewer than nine of the riders have been to you recently, have they not?—Yes, including the winner.

I suppose there may be great danger in manipulative surgery unless there is proper diagnosis?—Yes.

THE THEORY OF OSTEOPATHY

Replying to Lord ESHER, who asked if there had been any scientific examination of the theory of osteopathy, the witness said that he had examined thousands of spines and had the record of them in his case-books.

Lord DAWSON: Do you agree that any competition in throwing into the arena individual successes and failures serves no useful purpose in furthering knowledge?—WITNESS: Absolutely none.

And that is equally true whether it is medicine, or osteopathy, or herbalism, or anything else?—Yes.

If you want to test the truth of a theory there are definite methods which have been practised by all workers through the ages?—Yes.

MANIPULATIVE SURGERY

Replying further to Lord DAWSON, the witness said that fractures might be caused by manipulation in the wrong cases. There was bad manipulative surgery, comparable to bad osteopathic manipulation.

Lord DAWSON: Is it true to say that where harm occurs there has been faulty diagnosis?—WITNESS: Yes; faulty diagnosis and faulty technique.

Lord ELIBANK: Where did Sir Robert Jones get his idea of manipulative surgery in the first instance?—I think originally he got his desire to go in for this kind of treatment from a bonesetter—and so did I. Osteopaths did not exist then. When I first started to take an interest in manipulative surgery it was as a result of a bone-setter in Edinburgh. I think Sir Robert Jones's experience was the same in Liverpool. That was before osteopathy came to this country.

Replying further to Lord ELIBANK, the witness agreed that the practice of osteopathy was identical with the practice of manipulative surgery. Osteopathy was merely another name for manipulative surgery. But he did not agree that osteopathy was based on scientific thought and observation because the osteopaths had built up a pathology which, in his opinion, did not exist.

But you told us that the practice of osteopathy was identical with the practice of manipulative surgery. If manipulative surgery is based on scientific thought and observation why is not osteopathy?—WITNESS: Because the osteopath does not give the same pathology for the result of his manipulation as I do.

MANIPULATION AND FITNESS

The witness agreed with Lord Elibank that the same result would probably follow whether treatment was given by a manipulative surgeon or an osteopath if it was a case where manipulation would succeed. A large number of cases went to osteopaths. A large number of them were successful, but a large number were unsuccessful.

Lord MARLEY: Would you think that if patients followed your advice and came for an overhaul from time to time that the result of your examination and possible manipulation might be to prevent them from becoming ill?—WITNESS: It is difficult to answer yes or no. You probably do not realise that the fittest person in the world, if he has all the joints of his body manipulated, will get up and say that he feels good. He gets a feeling of well-being, but that will not prevent him getting pneumonia, or typhoid fever.

Would it not have a psychological effect?—The psychological effect would not prevent infection by the typhoid baccilus.

Lord MARLEY said he understood that a person in a good state of health was less likely to get disease and the witness agreed. If you are fit your resistance is definitely better than if you are not.

Lord MARLEY: Is there any human being structurally perfect?—WITNESS: Most decidedly not. You have only to look round this room. I train every child I can to stand and sit correctly. If you start young it has an amazing effect on their general health. As a rule, in a patient over 21, if he has not been taught to sit and stand correctly, it is too late to correct the spine. It was not necessary to have osteopaths to make children grow up properly.

Would it not help children to have regular examinations ?—They are examined and helped by the medical profession, but they take not the slightest notice. For children manipulation was not necessary. It was a question of training them to get their spine into the correct position.

THE OSTEOPATH'S TRAINING

The CHAIRMAN asked the witness whether he thought that a man who had spent five years studying the subjects prescribed in the Bill and who had passed the necessary examinations would still be unfit to make a diagnosis, and the witness replied that it would depend on the standard of the examinations. Ten years' training would not qualify a man if the standard of education was not right. How, he asked, could an osteopathic college be brought up to the standard of the universities, with their superior teaching, laboratory, and financial resources ?

This fear about the standard of education makes you fear that an osteopath qualified on that basis would not be able to make a proper diagnosis ?—Yes.

WITNESS agreed that if osteopaths had a minimal standard of medical education they would be valuable ancillaries to treatment.

Asked whether a register of qualified osteopaths would not be in the public interest the witness said that a register would not prevent any unregistered person giving osteopathic treatment so long as he did not call himself an osteopath and that immediately would defeat the object of a register.

Sir Farquhar Buzzard Recalled

Sir FARQUHAR BUZZARD, recalled, said that in the scientific world a claim for recognition must be accompanied by prima-facie evidence. There must be something to investigate. The volumes produced by the Still Research Institute had been examined in detail by a number of competent research workers and the conclusion reached was that they did not afford such evidence. It had been claimed before the Committee that skilled manipulation of the spine would prevent all disease and cure particular diseases in the early stages. If that was true it would constitute the greatest medical discovery during the last half-century, and the whole medical profession would welcome it with open arms—as they had welcomed every great discovery when its basic principles had been demonstrated. American scientists had had osteopathic schools and hospitals in their midst for fifty years, and would have gladly told the world that an American was the greatest discoverer of our age ; but every medical man of repute in that country—a country which had been the birthplace of many important scientific discoveries — repudiated the osteopathic creed Thousands of post-mortem examinations were conducted throughout the world every week by expert pathologists with the one object of finding abnormalities, and it was inconceivable that the osteopathic lesion had escaped their observation when, according to osteopaths, it was present in every person suffering from disease. Though the British School of Osteopathy had something that was called a pathological laboratory, it had not a single specimen illustrating the osteopathic lesion. America, said the witness, in conclusion, was a young country, and lack of experience had allowed individual States to be rushed into passing very unwise and very confused legislation in regard to various healing cults. But if Great Britain, with all her great traditions of sanity, at this period in her history were to follow the example of the United States in recognising these evanescent cults, she would undoubtedly be a laughing-stock among the nations. The first step was an easy one, but it made retreat exceedingly difficult, as America had already found to her cost.

Speaking of the memorandum submitted by about 800 scientists and teachers setting out reasons against the Bill, Mr. THORPE, counsel for the promoters, said he noticed that there were only 12 signatories from Edinburgh, where, he was told, there were 300 or 400 teachers. "Would I be right," he asked, "in saying that the majority of teachers at universities and medical schools have not signed ?"—The Witness : "Quite wrong."

HAS OSTEOPATHY BEEN INVESTIGATED ?

Replying to Mr. THORPE, the witness said he had no knowledge that the current doctrine of osteopathy had been investigated in any university laboratory in this country. The fact that osteopaths, by right or wrong methods, had brought relief to sufferers, did not constitute prima-facie evidence in favour of their theories.

COUNSEL : What is the minimum of prima-facie evidence that would be necessary to set in motion this great machinery that is always waiting to consider current theories ?

The witness replied by repeating his statement that if the American scientific side of the medical profession had found anything in the osteopathic creed it would have been heard of long ago.

COUNSEL : Quite apart from America, has any British school of research gone out of its way or spent a moment of time considering the theories advanced by osteopathy ?—WITNESS : No.

COUNSEL : Will you give the reason ?—WITNESS : I have given the reason. There is more than one reason. I explained that something which has been before scientific bodies for fifty years and which has received no recognition, would not seem to be a very likely field for further research.

COUNSEL later asked if it had never occurred to the research workers that it might be in the public interest to explode theories and practice which the witness believed to be wrong. Sir FARQUHAR BUZZARD replied that he hoped they were doing it. They had been doing it before this Committee started, and the question had been recently raised by the introduction of the Bill.

COÖPERATION AGAIN

Later in the cross-examination Mr. THORPE returned to the question of coöperation with osteopaths.

COUNSEL : The minute a man gets a medical degree he can practise osteopathy with impunity. He does not lose caste with his medical brethren ?—WITNESS : That depends entirely on a personal question. You cannot make a generalisation.

COUNSEL : If it is a fallacy, would not it be in the public interest to say that no one who comes under the control of the British Medical Association shall practise osteopathy ? Take a man like Dr. Macdonald who is an unashamed and unmitigated osteopath ; is it in the public interest that he should be allowed to continue these fallacious theories and practice ?—WITNESS : I cannot answer that question.

COUNSEL : I want your views.—WITNESS : I say "No."

Later the witness said he was expressing his own view. He could not object to his practising. He would say he did not think it was desirable to practise as a follower of Andrew Still.

COUNSEL remarked that Sir Henry Brackenbury was rather generous when he said that so far as the increasing recognition of manipulation and the limitation in the use of drugs was concerned he would like to give the osteopaths every credit for having emphasised these points. He asked the witness if he would go so far as that. The reply was : "I give it all the credit that is due."

Is any credit due?—I do not know.

That is most generous of you. Do you agree with Mr. Mennell that each branch of the profession has something to give to the other ?—Undoubtedly.

Questions from the Committee

Mr. RADCLIFFE, K.C., Counsel for the Royal Colleges, then examined Sir Farquhar Buzzard. The witness declared that if there was scientific evidence it could be produced in any country to medical societies and the like.

Lord Esher pointed out that Dr. Macdonald said he had endeavoured to get his theory examined and was ready to produce evidence of it, and the medical people had always refused to examine it. The witness said he knew that Dr. Macdonald had talked to medical societies and had the opportunity of putting forward in a categorical way the evidence which he considered scientific evidence.

Lord Elibank: Yet the medical societies have not thought it worth while to pursue the subject ?—Witness: Having heard it—no.

Lord Elibank: Is it not wrong that the Medical Council or medical societies have taken no notice in spite of the fact that osteopaths are practising all over the country ? —Witness: Why wrong ?

Lord Esher: Because you maintain that they are a danger to the community. What is scientific research for if it is not to protect the public ?—Witness: It is clear that we could have legislation against anybody practising the healing art who is not qualified, but as a matter of fact we have not got it. There is no legislative action against anybody practising the healing art. We cannot therefore protect the public in that way. The public can go to any cult but they take their own risk. At present they know where they can go to qualified medical men but they can go elsewhere if they like.

Lord Esher: I suppose you think medicine is securely based on science ?—Witness: I think it is.

Lord Esher: When did medicine become scientific ? —Witness: You could not give a date, but it has become more of a science than an art. There has been an enormous advance in the last hundred years.

The witness agreed that when they bled people and gave a lot of drugs it was a danger to the public, and he admitted it would have been a pity if medicine had then been discouraged and handicapped.

Lord Esher: And that is what you are now proposing to do with osteopathy ?—Witness: Yes.

Sir Farquhar Buzzard again pointed out that to say that large numbers of people had been cured was not prima-facie evidence. In the course of answers to Lord Dawson, he agreed that the crucial difference between manipulative surgery and osteopathy is that the former confines itself to a delimited sphere, whereas osteopathy claims all the diseases. This was the reason why the claims of osteopathy must be opposed.

Lord Esher asked whether osteopaths would be welcome if they put up their scientific case before the scientific people in this country after the inquiry. The witness replied that they would.

Lord Elibank: What chance would the osteopaths have if they put up their case, in view of the statement signed by so many teachers and scientists ? What chance would they have of proving anything ? Is not it prejudged in that statement ?—Witness: No. I do not admit prejudice against osteopathy but I am against it.

When the Committee met again on Monday, Sir Norman Walker, President of the General Medical Council, gave evidence on behalf of the Council. He submitted to the Committee a lengthy memorandum which the Chairman said would be included in the minutes of evidence.

Memorandum from the General Medical Council

This memorandum of evidence opened with a résumé of the conditions of practice in Great Britain and Ireland before the establishment in 1858 of a register of qualified medical practitioners, and the constitution of a Council to keep this register. It went on to describe the functions of the Council in regard to registration and medical education, and then, as the body entrusted with the care and maintenance of the Medical Register, to offer observations on the provisions of the Bill as it stands.

The Bill, the Council find, is one which appears to contemplate a departure from the policy hitherto pursued in legislation in regard to the practice of medicine in this country. The Medical Acts have not been directed to the creation of any monopoly in the healing art, but merely to ensuring the maintenance of a register designed to inform the public of the names of those persons who have carried out a sufficient curriculum and passed examination tests sufficient to justify the appellation " qualified." The standard required by the General Medical Council for qualification and registration has not remained stationary, but has steadily risen with the increase in medical knowledge. It would appear that the provisions of the Bill would create some confusion in the mind of the public, since the new register of osteopaths proposed to be set up would contain the names of persons whose standard of education varied from that laid down by the General Medical Council for medical practitioners; and the Bill would further appear to have the effect of substantially restricting the practice of medical practitioners registered under the Medical Acts in certain directions wherein they now practise freely.

CLAUSE 2.—" THE PRACTICE OF OSTEOPATHY "

The Council are unable to find in the Bill any definition of the scope of this practice or of the nature of that which is to be practised.

The omission from the Bill of any precise definition of osteopathy is, however, a matter of crucial importance to the public, for by Clause 8 of the Bill every person (whether a registered medical practitioner or not) who is not registered as an osteopath is prohibited under penalty from practising the undefined, or holding himself out as a practitioner of it, or as being prepared to practise it.

The Memorandum prefixed to the Bill (which would have no statutory effect if the Bill became law) appears to be intended to suggest (1) that there is an easily identifiable " art and science of healing as defined under this Bill " (Memorandum, line 22), and (2) that the proper definition, which is nowhere to be found in the text of the Bill, would be to the effect that osteopathy is " a developing system of treatment of disease by manipulative methods " (Memorandum, lines 2 and 3).

If this assumption be correct, what is proposed by the Bill is to prohibit large and increasing numbers of registered medical practitioners from practising in a branch of surgery which has been followed by qualified practitioners both before and since the passing of the Medical Acts. The minimum medical curriculum laid down in the resolutions of the Council specifically provides that every medical student shall receive (i) practical instruction in surgical methods, including mechano-therapeutics, and (ii) special instruction in orthopædics, if this is not included in the course of systematic instruction (also specifically prescribed) in the principles and practice of surgery, or in the course of instruction in surgical methods prescribed under (i).

Provision is made for the instruction of students in manipulative surgery by the medical schools in which candidates are prepared for the qualifying examinations of every licensing body. Various medical schools have established special departments for instruction in orthopædic surgery (including the use of manipulative methods). Various licensing bodies have instituted post-graduate diplomas in orthopædic surgery (including the use of manipulative methods) which recognise the special efficiency of the holders to practise this branch of surgery.

The intent and effect of the Bill appear to be on the one hand to exclude registered medical practitioners from a field of practice for which they possess the statutory qualification, and on the other hand to admit exclusively to this field persons who remain unqualified and unregistered because they have not gone through the courses of study and examinations requisite under the Medical Acts, to practise an undefined method of treatment.

The position of registered medical practitioners under the Bill is to be contrasted in this respect with the position of osteopaths under the Medical Acts, which contain nothing to prevent a registered medical practitioner from adopting any theory of medicine or surgery, including osteopathy, but contain (in section 28 of the Act of 1858) a provision specifically prohibiting the Council from erasing the name of any person from the Medical Register on the ground of his having adopted this or any other theory of medicine or surgery. In the enjoyment of the liberty thus secured to them by the Medical Acts, certain registered medical practitioners are understood to have adopted the theory of medicine or surgery known as osteopathy, and to have practised as osteopaths; but no question of the retention of their names on the Medical Register has been or can be raised on that ground.

Sir Norman Walker Examined

In reply to the CHAIRMAN, Sir Norman Walker said that he had been a member of the General Medical Council for 28 years and its president for three. Explaining the position in regard to medical reciprocity, he said that the term did not occur in any Act of Parliament. After a certain amount of previous preparation and after agreement had been reached, the Privy Council, if it thought fit, applied Part II of the Medical Act of 1886 to a particular country in respect of reciprocity. We have in this country, he said, medical reciprocity with two countries—Italy and Japan. In Japan, as in many oriental countries, there were grades of doctors; Japan only asked this country to accept the equivalent of its highest grade. In most other foreign countries it was necessary for a medical man to become naturalised before he could practise there. Part II of the Medical Act, 1886, was applied to any Dominion of the British Empire if they wished it. It was applied now to New Zealand, Australia, South Africa, and parts of Canada. Canadian medical legislation was not quite the same as our own, because each province had its own conditions. There was no medical reciprocity between us and the United States. The witness added that some years ago he went over to the United States to explore if there was any way of arriving at nearer reciprocity. There was in the United States a voluntary Association and National Board with medical examiners extending all over the States. Most of the States accepted their examination instead of their own. There was a joint agreement arrived at between the licensing bodies and the colleges in this country and the National Board, that they would each admit to their final examination graduates from both countries, but they must pass the examination.

CHAIRMAN: Must they take a course of training?—WITNESS: That depends upon the licensing body; I think all of them require some instruction in this country

NO MONOPOLY OF HEALING

Mr. THORPE, cross-examining the witness on behalf of the promoters, called his attention to a passage in his memorandum in which it was stated that the Medical Acts had not been directed to the creation of any monopoly in the healing art. He asked the witness to explain why he took that view.—WITNESS said that he could not regard the medical profession as possessing a monopoly. It was perfectly open for anyone to take the advice of any person he likes. The Medical Acts were passed to establish that there were certain people who had gone through certain regulations.

COUNSEL put it to the witness that he must accept the fact that there was a monopoly in regard to Government appointments.—WITNESS said that was so, because legislation had been passed confining those appointments to persons whose names appeared on the Medical Register.

COUNSEL: Your memorandum states that if this Bill was passed it would create confusion in the public mind. Why is that?—WITNESS said he certainly thought there would be some confusion if another register was introduced. Everyone would not differentiate between those who were on a register for one form of healing and those who were on another.

A ROYAL COMMISSION OF INQUIRY

Lord ELIBANK asked the witness if he would favour an investigation into the whole of the principles of osteopathy.

Sir NORMAN said he would have no objection to an investigation. I think, he added, that the history of medicine is very illuminating in this way. It took more than half a century to get the Medical Act through Parliament. There was an enormous number of Bills introduced into the House of Commons, and in 1881 the Government appointed a Royal Commission to inquire into the question. As a result the Act of 1886 was passed.

You suggest that the investigation should take the form of a Royal Commission.—I would be quite in favour of that.

Who in your judgment should sit on such Royal Commission; what class of people? Take the statement of Sir Farquhar Buzzard and the 800 people of great distinction in the scientific world who signed that statement to the effect that there could be no compromise between medical science and osteopathy; they were incompatible and contradictory; would those gentlemen who made that statement be reliable investigators of the principles of osteopathy if they were on a Royal Commission?—WITNESS said he thought there must be a general opinion, even among their Lordships, that it was very difficult to know what osteopathy was. But he certainly thought that there were a lot of names on the memorandum referred to who would be quite suitable to be members of such a Royal Commission.

You really think that you could get a Royal Commission on this subject that would be impartial and unprejudiced and which would examine the question with fresh minds?—WITNESS said he thought that such a Royal Commission could be set up.

I take it therefore that you do not rule out of your mind that there is possibly a great deal in osteopathy?—WITNESS said it was very difficult for a medical man trained as he had been as a pathologist to accept the theory of osteopathy.

Lord ESHER remarked that Sir Norman was the first medical witness who had been before the committee who had not shown prejudice against osteopathy without having examined it.

THE CURRICULUM

Asked by the CHAIRMAN to state his view about the proposed amendment of the Bill extending the period of osteopathic training from four to five years, Sir Norman said that for years the General Medical Council had been raising the standard of medical education. The Council did not act by compulsion, but rather followed methods of peaceful persuasion. All the teaching bodies now accepted five years as the minimum curriculum of study. The Council welcomed the attitude of some bodies who did not think that five years was enough. There were several universities which now required six years' medical study, and the G.M.C. had nothing to say but commendation.

As far as you are able to judge, do you think five years sufficient for the training of an osteopath?—If osteopathy is what it claims to be I think it would be well that the person practising should have gone through a curriculum as long as that for a medical degree.

The witness went on to say that the General Medical Council were now reviewing the reports of their inspectors to see whether there ought to be further changes in the medical curriculum. It was not unlikely that there might be changes made in the curriculum so far as the first two years were concerned. There was a strong feeling that certain parts of the curriculum had outlived their usefulness. As showing that medical schools were now providing instruction in manipulative surgery, the witness said that Liverpool was granting a Mastership of Surgery in Orthopædics. The medical profession were now devoting more attention to manipulative methods.

Lord REDESDALE asked if the teaching in the medical curriculum was directed to the prospect of the practitioner himself making use of it.—WITNESS: Yes. In the surgical out-patient department this is a very important part of the treatment.

ANÆSTHETISTS FOR OSTEOPATHS

Asked by the CHAIRMAN whether medical practitioners could act as anæsthetists for osteopaths, the witness said that it was rather a curious thing that while the public was very ready to take all kinds of advice from osteopaths and others, they had peculiar faith in medical men in regard to the administration of anæsthetics. It was not illegal for anyone to give anæsthetics. He agreed that the difficulty was that if a fatality occurred an unregistered man might get into trouble, whereas in the case of a medical man the presumption was in his favour. The only person whose name had been erased from the register for giving an anæsthetic for an unregistered man was Dr. Axham. All such charges were carefully gone into, and he decided whether the charge or complaint was such that the practitioner concerned should be asked for his side of the story, or rather, for an explanation. The practitioner was written to at his (the witness's) direction, and if the explanation seemed to him satisfactory he did not bother the Committee with it; but if it did not it went before a special Committee of the Council known as the Penal Cases Committee, which considered every aspect, and the only complaints which they sent in to the Council were those which in their judgment were serious.

Lord ESHER asked if the general effect of the Council's rules at the present time would frighten an anæsthetist from assisting Dr. Macdonald because he was an osteopath.—WITNESS: I do not think so. If a charge were made against a doctor of giving anæsthetics for a registered practitioner, even if he was an osteopath, I do not think that it would be sustained.

Lord REDESDALE pointed out that it had been stated to the Committee that some doctor refused to make a culture for Dr. Macdonald on the ground that he was practising as an osteopath.—WITNESS said that was narrow-mindedness.

CHAIRMAN: If a medical practitioner was making a practice of assisting an osteopath would he be liable to have his name erased from the register?—WITNESS: He would be liable to have his case considered.

But would he be liable to have his name struck off?—WITNESS: I cannot commit the Council. The Council, he added, was a judicial body, and it did not pronounce what it was going to do beforehand. If in terms of the standing orders and warning notice a practitioner was enabling an unregistered person to practice as if he were a qualified practitioner then he would be charged.

Prof. Gask's Evidence

Prof. G. E. GASK, director of the surgical unit at St. Bartholomew's Hospital, then gave evidence. Replying to Mr. RADCLIFFE, counsel for the Royal Colleges, he emphasised the importance of a thorough training in surgery for anyone who was to practise the healing art. Sometimes a disease would simulate an injury and sometimes an injury would simulate a disease, and it would be difficult and might be unsafe to make a diagnosis unless familiar with all forms of disease. It was not compatible with his experience to say that there was any one chief cause of disease. Re-examined by Mr. D. L. JENKINS, the witness spoke of his experience in post-mortem examinations extending over forty years. If the osteopathic lesion was detectable in such examinations it ought to have been detected.

Lord ESHER: You say you have never been able to find the osteopathic lesion. But you have not been looking for the osteopathic lesion for forty years. When did you start?—WITNESS: In the course of my work I have had to examine spines and look at them very carefully.

Lord ESHER: Yes, but were you looking at the spines with the osteopathic theory in mind?—WITNESS: I was looking at them to see if there was any deformity or any disease of any sort.

Lord ESHER: If you had been studying the osteopathic theory for forty years you would not have found it necessary to send for text-books on the subject for the purpose of this inquiry?—WITNESS: I had not been studying the theory from the standpoint that there was one chief factor in the causation of disease and that there was one chief cure.

Lord ESHER: Therefore you have not been making a complete study of the osteopathic theory?—WITNESS: Of the theory that there was one chief factor for the causation of disease, no.

EDUCATION FOR OSTEOPATHY

Lord ELIBANK: Much has been said about diagnosis. Do medical practitioners always prove to be right in their diagnosis of appendicitis? Are not many operations performed in which it is found that the appendix is quite clean and in good order?—WITNESS: It has been so.

The witness added that he did not know whether that happened in many cases and he could not give any statistics about it.

Lord ELIBANK: It seems to me that if the osteopath is a qualified man who has undergone the training indicated in the Bill he should be just as capable of diagnosis as a medical practitioner?—WITNESS: Qualified medical practitioners naturally make mistakes; they are only human. But is it not likely that the man who is fully trained to the practice of medicine would be less likely to make a mistake than one who is not fully trained in all its branches, or who studies one to the exclusion of others? We believe that a man should be thoroughly trained in all branches of the profession up to the limit of qualification.

Lord ELIBANK asked if the witness had studied the Schedule in the Bill setting out the course of study for osteopaths. Prof. Gask said he was not familiar with its details.

Lord ELIBANK: Do you mean to say that you have signed a document like this against the Bill without having read the Bill? I wonder how many more of the 1600 persons who have signed this document have read the Bill?—WITNESS: I have read the Bill, but I do not pretend to carry in my head the exact details of the curriculum proposed.

Lord ELIBANK: Is it fair to put out an uncompromising statement like that without having read the Bill properly?—I have nothing more to say.

In answering questions by Lord DAWSON, the witness said that he held that the training for osteopathy should be as good and as long as the training for medicine; and if that were so he thought there would be no necessity for two parallel systems. Replying to Lord REDESDALE, who asked if the art of diagnosis was not more in the nature of a flair than the result of education pure and simple, he said he thought proficiency in diagnosis was the result of many years of study of details. In this connection he did not think that there was any such thing as inborn intuition.

Sir ARTHUR ROBINSON, Permanent Secretary to the Ministry of Health, then submitted a memorandum on behalf of the Ministry.

Memorandum from the Ministry of Health

The Minister of Health desires to put briefly before the Select Committee certain considerations relevant to the proposal for the establishment of a Statutory Register of Osteopaths, and in making these observations he has had regard both to his general responsibility for the health of the people and to his special responsibility for the statutory health services.

WHAT IS THE NEED FOR A SEPARATE OSTEOPATHIC REGISTER?

Before the measure of recognition involved in the establishment of a statutory register is given to osteopathy, it appears to the Minister to be essential that there should be included in the statute a definition of the meaning of osteopathy so clear and precise as to enable it to be differentiated without possibility of mistake from other forms of practice. Unless this can be done proper administration of the register would seem to be impracticable.

It is noted that the Medical Act of 1858 and subsequent legislation have established in this country a system of medical registration based on the principle that all persons seeking admission to the privileges of the register should satisfy certain common standards of education and qualification. Persons lacking the registrable qualifications are not prohibited from practising the art of healing, but they are not entitled to hold themselves out to the public as qualified persons, nor can they sue for fees, nor sign statutory medical certificates. It would appear from the schedule to the Bill that the education and training considered necessary for the properly qualified osteopath correspond to a very large extent with the orthodox medical curriculum, and such correspondence appears to raise the question whether there is any sufficient reason for the establishment of a separate register and a separate system of education and qualification for osteopaths. Section 23 of the Medical Act, 1858, specifically guards against any attempt on the part of the licensing bodies to impose upon candidates an obligation either to adopt or refrain from adopting the practice of any particular theory of medicine or surgery, and there is nothing to prevent any person who has gained admission to the Medical Register from practising the art of healing according to the osteopathic theory.

APPROVAL TO AWAIT SUBSTANTIATION OF PRINCIPLES

If, on the other hand, as appears to be maintained, the practice of osteopathy rests upon a fundamental basis other than that of the subjects included in the medical curriculum under the Medical Acts, 1858 and 1886, it appears to the Minister to be incumbent on Parliament to satisfy itself, before giving its assent to the present Bill, that the specific principles and system of healing proposed to be employed by those who will be registered as osteopaths is one which can be properly and safely commended to the public.

It is not within the scope of this memorandum to discuss the scientific and technical issues which underlie the differences between the doctor and the osteopath, but the further elucidation of those issues seems to be a necessary preliminary to the passing of legislation which will confer upon the practice of osteopathy the seal of Parliamentary approval (a fortiori the granting of powers and privileges on such persons). It is understood that those who support the Bill justify it mainly on the ground that it will enable the public to distinguish the qualified osteopath from the unqualified. But the Bill, if passed, cannot fail to do more than that; it will inevitably convey an assurance that a person who has satisfied the statutory tests for admission to the Osteopaths' Register is a person who is, in all respects, well fitted to undertake the various and heavy responsibilities attaching to the treatment of disease. In other words, Parliament will have given some sort of guarantee of the validity of the principles upon which the osteopath exercises his craft. The Minister conceives that Parliament will require such a claim as is here involved to be first very fully investigated and substantiated.

DIFFICULTY OF RECOGNISING EXISTING QUALIFICATIONS

Apart from the scientific issues, there are certain practical consideration which, the Minister suggests, should be taken into account before such a proposal is carried into effect. According to the Bill, there are three classes of persons who will be admitted to the Register :—

(*a*) graduates or licentiates of a British school of osteopathy;

(*b*) holders of certificates granted in a British dominion or foreign country;

(*c*) persons who have been engaged in the practice of osteopathy for three years prior to the passing of the Act and are in the opinion of the Board of Registration fit and proper persons to be registered.

Evidence will no doubt be laid before the Select Committee as to the operations of the British School of Osteopathy, but, as the Minister understands, the register would, in the first instance, be composed for the most part of a comparatively small number of persons who hold American degrees in osteopathy and a much larger number of other persons registered under (*c*) above, all of whom would become entitled to describe themselves to the public as osteopaths registered by Act of Parliament. It is alien to the general principles which have so far been followed in comparable legislation (e.g., that relating to the registration of medical practitioners, dentists and nurses) to recognise qualifications conferred by foreign educational institutions, and it seems a matter for consideration whether a register composed in this fashion is one which Parliament should take the responsibility of commending to public notice. It is suggested that, apart from other and more fundamental considerations, the question of establishing a register of osteopaths by Act of Parliament might well be deferred until a system of education in the principles and practice of osteopathy has been more fully developed in this country by an institution or institutions over which Parliament (or the Board of Registration) would be able to exercise adequate powers of supervision, inspection and control.

On a minor point, it is observed that the Government Department to which it is proposed that the Board of Registration should be made responsible in respect of its regulations is the Ministry of Health. On the assumption that the operation of the Bill is not intended to be limited to England and Wales, it would seem more appropriate to follow the precedents of the Medical Acts and the Dentists Acts by bringing the Board within the jurisdiction of the Privy Council.

EFFECT OF DUAL REGISTRATION ON STATUTORY HEALTH SERVICES

The Minister has an interest in this matter, not only by virtue of his general responsibility for the public health, but also on account of any repercussions which the Bill might have upon certain statutory services for the efficient maintenance of which he is responsible to Parliament. Among the more important of these may be mentioned :—

(1) The accurate determination and certification of the causes of death.

(2) The correct diagnosis and certification of sickness under the National Health Insurance Acts.

(3) The correct diagnosis and certification of infectious disease for the purposes of the Public Health and Infectious Diseases Acts; and

(4) The proper discharge of the medical duties imposed by Act of Parliament on medical practitioners or administered by local authorities and their medical officers and advisers, including the Vaccination Acts, the Public Health Acts, the Mental Deficiency Acts, the Workmen's Compensation Act, and the Midwives Acts.

As regards the first of these, the Bill itself authorises certain classes of registered osteopaths to give certificates of the cause of death, and a separate memorandum by the Registrar-General on this subject is annexed hereto. The matters referred to under (2), (3) and (4) above are not touched directly by the Bill, but the Minister apprehends that the passage of the Bill into law would in all probability be followed sooner or later by further claims from the ostepaths, e.g., for the right to participate in insurance practice and to take a share in the various and important medical duties entrusted to medical practitioners by the Public Health Acts. This consideration strengthens the view of the Minister that further inquiry into the osteopathic system is very requisite.

PROPOSAL FOR A SCIENTIFIC INQUIRY

In the light of these considerations, it appears to the Minister that a sufficiently strong case has not been made out for the adoption of the proposals in the Bill at the present time, and that the proper action at present is to set on foot an organised and careful scientific inquiry into the principles and practice of osteopathy by a body suitable for the purpose. Should this view be taken, those who are now practising osteopathy would, pending the result of the inquiry, have the choice open to them, should they be dissatisfied with their present status, either of qualifying themselves for admission to the Medical Register or of constituting a voluntary register of osteopaths, and establishing, as soon as may be, effective training institutions in this country for the appropriate qualification of persons who may desire to be admitted to that register in the future.

Sir Arthur Robinson examined

Replying to the CHAIRMAN, the witness said that the sort of inquiry which the Minister had in mind would probably be an inquiry set up by the Medical Research Council, but there were various ways of conducting inquiries of this kind. The principal object of such an inquiry would be as to the validity of the claims of the osteopaths.

The Minister expresses no view about the Bill ?—It is not possible for me to say that because the spokesman of the Ministry of Health in the House of Lords debate did, taking all considerations into account, oppose the Bill. That was, I think, done with reference to these considerations and various other considerations as well.

In other words a Bill of this kind should be preceded by a thorough investigation as to the claims of the new science ?—Yes.

ADMISSION TO A REGISTER

The witness said that the Ministry had had some experience of statutory registers, and for practical purposes they had to expect that a large majority of the persons practising at the time did obtain admission to the register. The Ministry felt some doubt in this particular case with regard to the admission of persons in category " C," because they understood that one of the reasons of the State register was to safeguard the public. It appeared to them that on previous experience there would be a certain number of persons in practice admitted to the register whose admission, from the point of view of the safety of the public, might seem open to question.

The CHAIRMAN : You would draw a distinction between osteopaths who had no other qualification than three years' practice and persons practising dentistry and midwifery with similar qualifications ?—WITNESS : Yes, I think we should. In the other vocations you have normal training or practice in this country over a protracted period. It was perhaps easier to form a judgment as to the suitability of such persons for admission to a State register.

And so far as dentists and midwives are concerned their practice is limited in scope ?—That is another factor.

In reply to the CHAIRMAN, the witness said that if the Bill became law and they had on the one hand the registered medical practitioner and on the other hand the registered osteopath, a position of great difficulty would arise from the point of view of public health administration. There would then be a claim on the part of the osteopath to be placed in the same position as the medical practitioner with regard to the various services under the National Health Insurance Acts. From the point of view of the administrator that would be rather difficult unless there had been full inquiry into the training and the validity of the training of osteopaths.

The CHAIRMAN : To sum up, the view of the Minister is that before Parliament should be invited to sanction this Bill a Committee of Parliament itself must be satisfied that osteopathy is on a sound and scientific basis ?—WITNESS : Yes.

Lord ESHER : Was the Minister's view as to the need of having a scientific inquiry altered by the evidence given before this Committee ?—WITNESS : The Minister is indisposed at the moment and he has not been able to study the evidence laid before your Lordships. I should not advise the Minister to vary the memorandum on the evidence so far submitted.

The Minister does not consider it the function of this Committee to discover the truth or the validity of the osteopathic theory ?—It would, I think, be rather improper for me to express a view on that.

THE KIND OF INQUIRY

Answering Lord ELIBANK as to the kind of inquiry which the Minister had in mind, the witness said that the Minister thought that the Medical Research Council might not do the work itself, but set up a body to do it.

Who do this Council consist of ?—It is a committee of the Privy Council and consists of both a professional and lay element.

That is very important. From the evidence we have heard there seems to be a great prejudice in the minds of medical people against osteopathy *qua* osteopathy, and I should view with anxiety an inquiry conducted entirely by medical people.—I should think you could rely on the Medical Research Council to set up a body about the impartiality of which no reasonable man would have any doubt.

Replying further to Lord ELIBANK, the witness said he thought the essential point of the inquiry would be the validity or otherwise of the claim of the osteopaths. What followed on that would depend on the decision on the essential point. Pending an inquiry, if the osteopaths wished to differentiate those of their members who were very reliable, they could do what the members of other arts had done, and set up their own register.

Lord ELIBANK : You would recommend that ?—WITNESS : I neither recommend it nor disapprove it but if I was an osteopath that is what I should do.

ATTITUDE OF THE MINISTRY

In reply to Mr. THORPE, counsel for the promoters, the witness said the Ministry of Health recommended an organised and careful scientific inquiry, but it was perfectly neutral on the question whether there was a claim or not.

There is some prima facie evidence which justifies you in putting that forward ? You do not recommend inquiries unless there is something to be inquired into ?—There have been various Bills proposed on this question over a certain number of years and the Ministry has been called often to express such judgment as it could on the issue. We thought the time had come to have such an inquiry.

You have had no assistance from the official medical profession ?—There are medical men on the establishment of the Ministry of Health, and obviously before this memorandum was written the advice of those medical men was taken.

If there was some good in osteopathy your department need not look askance at it because it would involve additional administrative burdens ?—It would be for the department to do whatever was required of it. Assuming that there is something in the theory and practice of osteopathy, you have to consider whether that should not be superimposed on the medical curriculum. There are other ways of doing it in which administration would be more simple.

In reply to Mr. DICKENS, on behalf of the British Medical Association, the witness said the department had never asked the medical profession for assistance in ascertaining whether there was anything in the practice and theory of osteopathy. The British Medical Association would be called upon in the ordinary course to give evidence at the proposed inquiry but would not be called upon to give financial assistance. He should himself feel it necessary to get more clarity into the Bill. If this practice was to be differentiated from others the definition would not satisfy him. There would be difficulty if they came to administer it.

There are a great number of people who desire treatment by osteopaths. Do you conceive it possible that if osteopaths were placed on a register it would be impossible to refuse their services as part of the State machinery in connexion with national health ?—I think it would be quite impossible.

In other words an osteopath panel would have to exist side by side with medical panels ?—That is so.

The witness added that if they had the setting up of this register they would have to envisage giving the same privileges to a person on the one register as to a person on the other register.

Supposing a register of osteopaths was granted, without any preliminary investigation and without the claim of osteopathic theory having made good, as osteopaths sought to be done by this Bill, could you see any reason why a similar register should be refused to believers in other forms of treatment—chiropractors, Christian scientists, nature curers, and so on ?—If you give this inquiry you obviously strengthen the claim of other artists to similar treatment.

Memorandum from the Registrar-General

Accompanying the memorandum of the Ministry of Health was a supplementary memorandum from the Registrar-General taking exception to the provisions in Clause 7 (2) of the Bill empowering certain classes of registered osteopaths (*a*) "to sign certificates of birth"; (*b*) "to certify the cause of death"; and (*c*) "to sign certificates of death." The Registrar-General finds the Bill does not make clear its intention under (*a*) and (*c*), but under (*b*) important public interests are involved. The medical certificate of cause of death is the foundation of two separate systems contributing to the national welfare, both of great value to the community.

CERTIFICATION OF THE CAUSE OF DEATH

In the first place this certificate is the only means by which deaths attended by specific features needing investigation or inviting suspicion can, as a matter of routine machinery, be linked up with the scheme of public safety embodied in the coroners' system. It is the registrar's duty to report to the coroner, not only deaths of which the causes are wholly uncertified, but also every death of which the certified cause discloses any one of a series of prescribed indications bearing upon the presence of industrial diseases, the prevalence of particular kinds of accident or the possibility of some form of crime or violence. The efficiency of this system depends entirely upon the quality of the material on which it relies.

Secondly, this certificate is the raw material of the extensive body of medico-statistical (mortality) intelligence which plays so important a part in the promotion of the public health. It is hardly too much to say that there is no question or problem, either of health administration or of research into the causation of disease, in which these statistics do not form at least an indispensable background, if not a source of actual illumination. In this instance, also, a great deal depends upon the quality of the certificates, and thus upon the judgment, training, and experience of the practitioners whose conclusions they express.

NO MARGIN OF EFFICIENCY CAN BE GIVEN AWAY

The position, the Registrar-General concludes, accordingly stands thus. The paramount consideration is the quality of the certificates of cause of death; too much depends upon them to permit of any risks being taken in this respect for the sake of improving the position of a particular class of practitioners. If the provisions of the Bill, in fact, secured that the practitioners to whom it entrusts the function of certifying were as a class not inferior to the present class of registered medical practitioners, either in the possession of a trained judgment or in the breadth and extent of their professional education, no question could of course arise. But nothing less will serve. The certification of cause of death is not a simple matter. The standard already reached is still very far from perfection; and the responsible authorities recognise that improvement is desirable and are continually seeking to achieve it. There is thus no margin of efficiency which can be given away—no handicap which can be safely accepted. No opinion is or can be expressed in this memorandum as to the curriculum embodied in the Bill or as to the standard of competence which would be ensured by the provisions of the Bill as a whole in the body of practitioners whom it permits to certify. But in principle the touchstone is a simple one. Unless the new class of certifying practitioners is as fully equipped as the present class of registered medical practitioners in all those respects of training and experience which go to form a sound opinion of the causation of death, their admission must result in prejudice to the important public interests served by these certificates in regard to both public safety and medico-statistics.

Mr. Vivian examined

Mr. S. P. VIVIAN, the Registrar-General, then gave evidence in support of the memorandum submitted by him. He said it was desirable that the practitioners who furnished certificates of death should not be less qualified in regard to theories and practice, which formed the capacity to form a judgment, than the present medical profession. He attached considerable importance to the certificate of death. Not only was there the maintenance of security, but death certificates entered into medical surveys and statistics. The medical profession had agreed upon a catalogue of fatal diseases capable of the classification of mortality. If osteopaths were led to say spinal disease or something which came entirely outside present considerations that would involve a different view of the causes of disease and of death, and would have a very important effect on the value of statistics.

THE CHAIRMAN: *In the event of the Bill going through there would have to be some concordat arrived at whereby the two classes of practitioner must have some agreement as to the causes of death ?*—WITNESS: If that was possible. We want exact statements in the statistics.

You look to death certificates to provide material for further investigation ?—Yes. I had not heard that proposals are put forward to leave out the clause which deals with the certification of the cause of death but we thought it necessary to put those views on record.

Mr. THORPE: *No osteopath has ever said that a person died of a spinal lesion ?*—I do not know that. I take it from you. At present there is an exhaustive catalogue of diseases which is agreed upon by the medical profession of the country.

Mr. Elmslie examined

Mr. REGINALD C. ELMSLIE, surgeon in charge of the orthopædic department of St. Bartholomew's Hospital, in reply to Mr. JENKINS, counsel for the Royal Colleges, said that he and his colleagues on the council of the Royal College of Surgeons of England objected to the establishment of an osteopaths' register because it seemed impossible within a reasonable time to arrange for osteopathic training in any way equivalent to the education of the medical practitioner, and also because manipulative treatment—which might be dangerous in the hands of persons insufficiently trained in diagnosis —was already widespread, and available when required. He classified osteopaths in three groups. First were those with a medical qualification: nobody would take exception to their registration, but there were only five in this country. Secondly came those who had taken a diploma in osteopathy in this country, and he thought, from the account given to the Committee, that the training at the British School of Osteopathy would not justify their being included in a register. The third group were those trained in American colleges—some of them acceptable to the British Association of Osteopaths and some not. The witness did not see how a line could be drawn between minor and major surgical operations and maintained that a knowledge of major surgery was essential to diagnosis. Any one who was going to use manipulative treatment ought also to be educated in obstetrics and gynæcology. He did not think a system of education for osteopaths comparable to that available for medical students could be set up in less than five or even ten years.

According to osteopathy, Mr. Elmslie continued, manipulation of the spine might have a general effect. For instance, disease of the foot might require manipulation of the spine. But in all general diseases it was irrational to treat by manipulation a part which had no physiological association with the disease. The osteopath did not take the steps to arrive at an accurate diagnosis that would be taken by the medical man. If osteopathy was a complete system of healing, based on new theories of disease, then every osteopath should have a qualification which was given to every medical man. If it was a system of manipulative treatment it ought to be an ancillary treatment. The witness went on to describe the position of the Chartered Society of Massage and Medical Gymnastics which illustrated, he said, how a party of professional people, keeping to strict rule, could get its own organisation without having any State protection at all.

In cross-examination by Mr. Thorpe for the promoters of the Bill, Mr. Elmslie said that a great deal of what is described as osteopathy is founded on manipulative surgery.

Counsel: You said the osteopathic educational standard was not high enough. Would it not be desirable that people who have reached a high standard should be registered?—Witness: Yes.

Counsel: Then what *is* your real objection to the proposals of this Bill?—Witness: That register would consist of five names.

Counsel: You say they would not be qualified unless they were qualified as doctors?—Witness: Of the people whom it is proposed to register there are five who I know have the qualifications.

Counsel: Supposing osteopaths say that a great deal of the education does not help them in the practice of osteopathy?—Witness: If they did say so I should criticise it very strongly.

Mr. Souttar's Evidence

Mr. H. S. Souttar, also a member of the council of the College of Surgeons, and chairman of the Representative Body of the B.M.A., described in some detail the clinical side of the medical student's training. This was something more than a schedule, he said, and an essential part of it was that the student must have at his disposal a very large organisation. Without such facilities it was impossible in his opinion to become a doctor. At the root of the objection to the registration of osteopaths, however, was another feeling—namely, that osteopathy was essentially fraudulent. A statement was made for which no foundation whatever could be produced —no tangible foundation at all—and on that statement a whole system was built and men achieved their own advancement and remuneration. This statement that a small bone in the spine was out of place was absolute nonsense. It seemed to be generally accepted as a basis of osteopathy that all disease was due to small displacements of the spine. But there was no evidence in favour of this view, and to continue to make that statement without evidence was to expose oneself to a charge of fraud. That was the difficulty in the recognition of osteopathy. Five years' training would not make the slightest difference.

At this stage in the witness's evidence the Committee adjourned.

NOTES ON CURRENT TOPICS

In the House of Lords on April 2nd the Criminal Lunatics (Scotland) Bill was read the third time.

HOUSE OF COMMONS

WEDNESDAY, APRIL 3RD

Yellow Fever on the West Coast of Africa

Colonel Heneage asked the Secretary of State for the Colonies if he had any information to give as to the outbreak of yellow fever on the West Coast of Africa; if the outbreak was now stopped; and if the necessary help from research stations and personnel at home had been promptly forthcoming.—Sir Philip Cunliffe-Lister replied: Yellow fever is endemic among the natives of West Africa, and thus it is not, strictly speaking, correct to refer to an "outbreak of yellow fever." During the past few months cases of yellow fever have been reported from each of the four West African Dependencies. In the Gambia the first case diagnosed as one of yellow fever (European) proved fatal on Oct. 6th, 1934, and later three other Europeans also succumbed, among whom were Mr. Parish, the Colonial Secretary, and Mr. Hamlyn, Assistant Colonial Secretary. Three African cases were also notified, of which one proved fatal. The usual precautions were taken to deal with this situation, and the Island of St. Mary was placed in quarantine. The order declaring the island an infected district was cancelled on Jan. 18th, since when no further cases have been reported. In this connexion, I would refer to a reply which I gave on Dec. 21st. Between Nov. 21st and Jan. 15th five African cases of yellow fever were notified from the Gold Coast, of which two proved fatal. On Dec. 24th it was reported that two Europeans were suffering from yellow fever in Kano, in Northern Nigeria, but both have since recovered. Previous to this, three Europeans had died at Kano, and it is suspected that they were suffering from yellow fever. A number of African cases, of which one proved fatal, were also notified, and the usual precautions were taken to prevent the spread of infection. On Jan. 21st a suspected case of yellow fever, which was later confirmed, was reported from Sierra Leone. The victim in this case was a European who died on Jan. 26th. With regard to the second part of the question, I am able to say that no new cases have occurred since the middle of January. To combat this disease in the Gambia, assistance was obtained in the first place from the Gold Coast and from Sierra Leone. I should like to take this opportunity of expressing my thanks, and the gratitude of the Government of the Gambia, to Dr. Howells of the Gold Coast, and to Dr. Davey and Dr. Duncan of Sierra Leone, for the zeal and energy with which they handled a difficult situation, and to the Wellcome Research Institution, who kindly gave permission for Dr. G. M. Findlay to visit Bathurst in order to conduct inoculations against yellow fever. The Governor reports that "apart from the inoculations (152 persons in all were successfully inoculated) Dr. Findlay worked tirelessly, investigating the cause and extent of the outbreak, and also gathering a mass of data relating to the incidence of yellow fever and other diseases for scientific examination in London. It would be difficult to express our thanks too warmly or to exaggerate the importance to West Africa of the conclusions to be drawn from his work here."

THURSDAY, APRIL 4TH

Re-pasteurisation of Milk

Major Mills asked the Minister of Health if he was aware that some distributors of milk collected milk at country depôts at considerable distances from London and pasteurised it there; that they then transported it to London in bulk and pasteurised it again to nullify the effects of contamination and deteriorisation before bottling it for distribution; and whether he was satisfied that this second pasteurisation was a desirable practice in the interests of the health of the consumers.—Mr. Shakespeare replied: My right hon. friend is advised that it is undesirable that milk should be heat-treated more than once, and he was not aware that this procedure is adopted at the present time. It is one of the conditions of the sale of milk as "pasteurised" that the milk should not be heated more than once, and if my hon. friend will supply any evidence of an infringement of this condition my right hon. friend will bring it to the notice of the appropriate local authority.

Malnutrition in Durham

Mr. Batey asked the Minister of Health what action he proposed to take on the report made on behalf of the President of the Board of Education and himself regarding the condition of children suffering from malnutrition in the county of Durham; and whether it was intended to publish the report.—Mr. Shakespeare replied: This report is now being printed with a view to publication. The question of any action to be taken on the findings in the report is under consideration.

Accident Proneness of Motorists

Captain Erskine-Bolst asked the Minister of Transport whether any date had been fixed for the conference between motor insurance experts and representatives of the Medical Research Council to discuss the accident-proneness of motorists; and if he can state exactly what the agenda at this conference would be.—Mr. Hore-Belisha replied: Arrangements have been made for a conference to be held at the end of this week between representatives of the Medical Research Council and of Authorised Insurers for informal discussion of the paragraphs in the report of the Medical Research Council (Cmd. 4796) which deal with Accident-Proneness and Road Dangers.

MONDAY, APRIL 8TH

Price of Milk to Institutions in Scotland

Mr. Burnett asked the Secretary of State for Scotland whether he was yet in a position to make a statement as to the conclusions of the committee of investigation for Scotland regarding the price of milk to institutions which was the subject of a report of the Consumers' Committee.—Sir G. Collins replied: I have received the Committee's report, which is under consideration. The committee find that to the extent that local authorities and voluntary hospitals within the area of the Scottish Milk Scheme are now required to pay substantially more for their supplies of milk than they paid before the inauguration of the scheme, the price scale determined by the Board, and their action in giving effect to it may be regarded as contrary to the interests of the said local authorities and voluntary hospitals. With respect to the question whether the determination of the Board in this matter was not in the public interest, the committee find themselver unable to give an unqualified answer. The committee see no justification for the argument that because prior to the scheme a consumer was in a position, owing to the conditions then prevailing, of securing milk at less than economic rates, that fact should be regarded as a reason for fixing lower prices now that the scheme is in operation. The committee also have no hesitation in deciding that the beneficent nature of the work carried out by the local authorities and the voluntary hospitals does not in itself justify a claim to obtain their supplies of milk under the scheme at less than a reasonable price. On the other hand, the committee point out that it would be an unfortunate sequel to the scheme if the consumption of Grade A (T.T.) milk were abandoned to any extent in hospitals or in rate-supported institutions in favour of ordinary milk, and equally unfortunate if the consumption of milk, of whatever grade, were to be reduced. This consideration, coupled with the facts that the institutions are large consumers and do not purchase for trading purposes or for sale at a profit, that there is little expense involved in handling or distribution, and that there is no risk of any bad debts being made by the sellers, suggests to the committee that there is a case for exceptional treatment of these institutions in certain directions. In so far as these institutions have not received such treatment owing to the action of the Board, such action may be said to be not in the public interest.

Dangers of another Drought

Mr. Cleary asked the Minister of Health what steps were being taken to safeguard the country against the dangers of another possible drought.—Mr. Shakespeare replied: The average total rainfall for the country as a whole for the six months ended March 31st last, the critical months for the replenishment of water supplies, was above the normal, and urban water undertakers generally are in a good position. Should the necessity arise, powers are available to them to obtain additional water supplies with despatch under the Water Supplies (Exceptional Shortage Orders) Act, 1934, which remains in force until the end of the present year. The primary need in the rural areas is for permanent supplies. Good progress is being made under the Act of last year, and the total capital cost of schemes for which State grants have been provisionally allccated is now £3,200,000 for schemes in 1100 parishes.

TUESDAY, APRIL 9TH

Certified and Grade A (T.T.) Milk in Scotland

The Duchess of Atholl asked the Secretary of State for Scotland if he could now intimate the decision of the investigating committee in regard to the complaint made by the Association of Certified and Grade A (T.T.) Milk Producers in regard to the Scottish Milk Marketing Scheme.—The Lord Advocate replied: The findings of the committee were announced in reply to a question on Feb. 20th. An Order will now be made to give effect to the proposal that the contribution payable in respect of certified milk sold as such should be at the rate of one half-penny a gallon, with retrospective effect as from May 1st, 1934.

Medical Requirements on Renewal of Air Licences

Mr. Everard asked the Under-Secretary of State for Air whether the recommendation of the Gorell Committee on the subject of the medical requirements on the renewal of B licences by captains of large air-liners had been put into effect.—Sir P. Sassoon replied: The Air Ministry is prepared to put this recommendation into effect in appropriate cases.

Supply of Milk in Nursery Schools

Mr. Smedley Crooke asked the Parliamentary Secretary to the Board of Education what proportion of the nursery schools in the country were regarded as full-time schools and so eligible to receive milk at reduced rates.—Mr. Ramsbotham replied: All the 61 nursery schools recognised for grant by the Board of Education are regarded as full-time schools, and are eligible to participate in the scheme for the supply of milk at reduced rates. I have no information as to the number of unrecognised nursery schools, and am therefore unable to state the proportion of the grant-earning schools to the total number of schools which might be regarded as nursery schools.

Health Insurance Rights

Mr. Sutcliffe asked the Minister of Health whether his attention had been called to the number of cases in which insured persons lost the entire amount of their contributions over a long period of years owing to the fact that shortly before attaining the age of 65 they started some small business of their own; and whether, when they ceased to be insured employees, their approved societies notified them that they could preserve their rights by continuing as voluntary contributors.—Mr. Shakespeare replied: My right hon. friend is aware that every half-year a number of persons, after having been insured for a period of years as employed contributors, take up business on their own account, and after a free period of insurance of about 21 months can only retain their rights under the schemes of health insurance and contributory pensions by becoming voluntary contributors. Approved societies have been instructed to inform their members of the position, and my right hon. friend has no reason to think that they fail to do so.

Middlesex Hospital.—The new buildings of Middlesex Hospital are to be opened by the Duke of York on May 29th. He will be accompanied by the Duchess.

Kent and Sussex Hospital.—Criticism which had been levelled against the governors of the Kent and Sussex Hospital, Tunbridge Wells, in spending a sum of £188,422—£200,000 was the original approximate figure—on the erection of a new building on the Great Culverden site, was largely dispelled at the first annual meeting held at the hospital on March 21st. Incorporated in the new building are the Tunbridge Wells General Hospital, the parent institution founded 107 years ago, the Eye and Ear Hospital, and the Kent and Sussex Hospital, and as a whole is now known as the Kent and Sussex Hospital. The building has accommodation for 204 patients, and recently no fewer than 202 beds were in occupation on one day, giving an answer to the suggestion that the governors were not justified in providing for such a number. Furthermore, there is accommodation for 18 private patients, and as many as 14 have already been occupied at one time. Naturally, with the occupation of a new hospital, expenditure had been heavy, and equipment cost more than had been estimated, but the amount in excess of income was met by a number of legacies. The building fund marked an overdraft at the bank of £23,000, but there were the proceeds of the sale of the old General Hospital and site still to be realised.

of healing, based on new theories of disease, then every osteopath should have a qualification which was given to every medical man. If it was a system of manipulative treatment it ought to be an ancillary treatment. The witness went on to describe the position of the Chartered Society of Massage and Medical Gymnastics which illustrated, he said, how a party of professional people, keeping to strict rule, could get its own organisation without having any State protection at all.

In cross-examination by Mr. Thorpe for the promoters of the Bill, Mr. Elmslie said that a great deal of what is described as osteopathy is founded on manipulative surgery.

COUNSEL: You said the osteopathic educational standard was not high enough. Would it not be desirable that people who have reached a high standard should be registered ?—WITNESS: Yes.

COUNSEL: Then what is your real objection to the proposals of this Bill ?—WITNESS: That register would consist of five names.

COUNSEL: You say they would not be qualified unless they were qualified as doctors ?—WITNESS: Of the people whom it is proposed to register there are five who I know have the qualifications.

COUNSEL: Supposing osteopaths say that a great deal of the education does not help them in the practice of osteopathy ?—WITNESS: If they did say so I should criticise it very strongly.

Mr. Souttar's Evidence

Mr. H. S. SOUTTAR, also a member of the council of the College of Surgeons, and chairman of the Representative Body of the B.M.A., described in some detail the clinical side of the medical student's training. This was something more than a schedule, he said, and an essential part of it was that the student must have at his disposal a very large organisation. Without such facilities it was impossible in his opinion to become a doctor. At the root of the objection to the registration of osteopaths, however, was another feeling—namely, that osteopathy was essentially fraudulent. A statement was made for which no foundation whatever could be produced —no tangible foundation at all—and on that statement a whole system was built and men achieved their own advancement and remuneration. This statement that a small bone in the spine was out of place was absolute nonsense. It seemed to be generally accepted as a basis of osteopathy that all disease was due to small displacements of the spine. But there was no evidence in favour of this view, and to continue to make that statement without evidence was to expose oneself to a charge of fraud. That was the difficulty in the recognition of osteopathy. Five years' training would not make the slightest difference.

At this stage in the witness's evidence the Committee adjourned.

NOTES ON CURRENT TOPICS

In the House of Lords on April 2nd the Criminal Lunatics (Scotland) Bill was read the third time.

HOUSE OF COMMONS

WEDNESDAY, APRIL 3RD

Yellow Fever on the West Coast of Africa

Colonel HENEAGE asked the Secretary of State for the Colonies if he had any information to give as to the outbreak of yellow fever on the West Coast of Africa; if the outbreak was now stopped; and if the necessary help from research stations and personnel at home had been promptly forthcoming.—Sir PHILIP CUNLIFFE-LISTER replied: Yellow fever is endemic among the natives of West Africa, and thus it is not, strictly speaking, correct to refer to an "outbreak of yellow fever." During the past few months cases of yellow fever have been reported from each of the four West African Dependencies. In the Gambia the first case diagnosed as one of yellow fever (European) proved fatal on Oct. 6th, 1934, and later three other Europeans also succumbed, among whom were Mr. Parish, the Colonial Secretary, and Mr. Hamlyn, Assistant Colonial Secretary. Three African cases were also notified, of which one proved fatal. The usual precautions were taken to deal with this situation, and the Island of St. Mary was placed in quarantine. The order declaring the island an infected district was cancelled on Jan. 18th, since when no further cases have been reported. In this connexion, I would refer to a reply which I gave on Dec. 21st. Between Nov. 21st and Jan. 15th five African cases of yellow fever were notified from the Gold Coast, of which two proved fatal. On Dec. 24th it was reported that two Europeans were suffering from yellow fever in Kano, in Northern Nigeria, but both have since recovered. Previous to this, three Europeans had died at Kano, and it is suspected that they were suffering from yellow fever. A number of African cases, of which one proved fatal, were also notified, and the usual precautions were taken to prevent the spread of infection. On Jan. 21st a suspected case of yellow fever, which was later confirmed, was reported from Sierra Leone. The victim in this case was a European who died on Jan. 26th. With regard to the second part of the question, I am able to say that no new cases have occurred since the middle of January. To combat this disease in the Gambia, assistance was obtained in the first place from the Gold Coast and from Sierra Leone. I should like to take this opportunity of expressing my thanks, and the gratitude of the Government of the Gambia, to Dr. Howells of the Gold Coast, and to Dr. Davey and Dr. Duncan of Sierra Leone, for the zeal and energy with which they handled a difficult situation, and to the Wellcome Research Institution, who kindly gave permission for Dr. G. M. Findlay to visit Bathurst in order to conduct inoculations against yellow fever. The Governor reports that "apart from the inoculations (152 persons in all were successfully inoculated) Dr. Findlay worked tirelessly, investigating the cause and extent of the outbreak, and also gathering a mass of data relating to the incidence of yellow fever and other diseases for scientific examination in London. It would be difficult to express our thanks too warmly or to exaggerate the importance to West Africa of the conclusions to be drawn from his work here."

THURSDAY, APRIL 4TH

Re-pasteurisation of Milk

Major MILLS asked the Minister of Health if he was aware that some distributors of milk collected milk at country depôts at considerable distances from London and pasteurised it there; that they then transported it to London in bulk and pasteurised it again to nullify the effects of contamination and deteriorisation before bottling it for distribution; and whether he was satisfied that this second pasteurisation was a desirable practice in the interests of the health of the consumers.—Mr. SHAKESPEARE replied: My right hon. friend is advised that it is undesirable that milk should be heat-treated more than once, and he was not aware that this procedure is adopted at the present time. It is one of the conditions of the sale of milk as "pasteurised" that the milk should not be heated more than once, and if my hon. friend will supply any evidence of an infringement of this condition my right hon. friend will bring it to the notice of the appropriate local authority.

Malnutrition in Durham

Mr. BATEY asked the Minister of Health what action he proposed to take on the report made on behalf of the President of the Board of Education and himself regarding the condition of children suffering from malnutrition in the county of Durham; and whether it was intended to publish the report.—Mr. SHAKESPEARE replied: This report is now being printed with a view to publication. The question of any action to be taken on the findings in the report is under consideration.

Accident Proneness of Motorists

Captain ERSKINE-BOLST asked the Minister of Transport whether any date had been fixed for the conference between motor insurance experts and representatives of the Medical Research Council to discuss the accident-proneness of motorists: and if he can state exactly what the agenda at this conference would be.—Mr. HORE-BELISHA replied: Arrangements have been made for a conference to be held at the end of this week between representatives of the Medical Research Council and of Authorised Insurers for informal discussion of the paragraphs in the report of the Medical Research Council (Cmd. 4796) which deal with Accident-Proneness and Road Dangers.

MONDAY, APRIL 8TH

Price of Milk to Institutions in Scotland

Mr. BURNETT asked the Secretary of State for Scotland whether he was yet in a position to make a statement as to the conclusions of the committee of investigation for Scotland regarding the price of milk to institutions which was the subject of a report of the Consumers' Committee.—Sir G. COLLINS replied: I have received the Committee's report, which is under consideration. The committee find that to the extent that local authorities and voluntary hospitals within the area of the Scottish Milk Scheme are now required to pay substantially more for their supplies of milk than they paid before the inauguration of the scheme, the price scale determined by the Board, and their action in giving effect to it may be regarded as contrary to the interests of the said local authorities and voluntary hospitals. With respect to the question whether the determination of the Board in this matter was not in the public interest, the committee find themselver unable to give an unqualified answer. The committee see no justification for the argument that because prior to the scheme a consumer was in a position, owing to the conditions then prevailing, of securing milk at less than economic rates, that fact should be regarded as a reason for fixing lower prices now that the scheme is in operation. The committee also have no hesitation in deciding that the beneficent nature of the work carried out by the local authorities and the voluntary hospitals does not in itself justify a claim to obtain their supplies of milk under the scheme at less than a reasonable price. On the other hand, the committee point out that it would be an unfortunate sequel to the scheme if the consumption of Grade A (T.T.) milk were abandoned to any extent in hospitals or in rate-supported institutions in favour of ordinary milk, and equally unfortunate if the consumption of milk, of whatever grade, were to be reduced. This consideration, coupled with the facts that the institutions are large consumers and do not purchase for trading purposes or for sale at a profit, that there is little expense involved in handling or distribution, and that there is no risk of any bad debts being made by the sellers, suggests to the committee that there is a case for exceptional treatment of these institutions in certain directions. In so far as these institutions have not received such treatment owing to the action of the Board, such action may be said to be not in the public interest.

Dangers of another Drought

Mr. CLEARY asked the Minister of Health what steps were being taken to safeguard the country against the dangers of another possible drought.—Mr. SHAKESPEARE replied: The average total rainfall for the country as a whole for the six months ended March 31st last, the critical months for the replenishment of water supplies, was above the normal, and urban water undertakers generally are in a good position. Should the necessity arise, powers are available to them to obtain additional water supplies with despatch under the Water Supplies (Exceptional Shortage Orders) Act, 1934, which remains in force until the end of the present year. The primary need in the rural areas is for permanent supplies. Good progress is being made under the Act of last year, and the total capital cost of schemes for which State grants have been provisionally allocated is now £3,200,000 for schemes in 1100 parishes.

TUESDAY, APRIL 9TH

Certified and Grade A (T.T.) Milk in Scotland

The Duchess of ATHOLL asked the Secretary of State for Scotland if he could now intimate the decision of the investigating committee in regard to the complaint made by the Association of Certified and Grade A (T.T.) Milk Producers in regard to the Scottish Milk Marketing Scheme.—The Lord ADVOCATE replied: The findings of the committee were announced in reply to a question on Feb. 20th. An Order will now be made to give effect to the proposal that the contribution payable in respect of certified milk sold as such should be at the rate of one half-penny a gallon, with retrospective effect as from May 1st, 1934.

Medical Requirements on Renewal of Air Licences

Mr. EVERARD asked the Under-Secretary of State for Air whether the recommendation of the Gorell Committee on the subject of the medical requirements on the renewal of B licences by captains of large air-liners had been put into effect.—Sir P. SASSOON replied: The Air Ministry is prepared to put this recommendation into effect in appropriate cases.

Supply of Milk in Nursery Schools

Mr. SMEDLEY CROOKE asked the Parliamentary Secretary to the Board of Education what proportion of the nursery schools in the country were regarded as full-time schools and so eligible to receive milk at reduced rates.—Mr. RAMSBOTHAM replied: All the 61 nursery schools recognised for grant by the Board of Education are regarded as full-time schools, and are eligible to participate in the scheme for the supply of milk at reduced rates. I have no information as to the number of unrecognised nursery schools, and am therefore unable to state the proportion of the grant-earning schools to the total number of schools which might be regarded as nursery schools.

Health Insurance Rights

Mr. SUTCLIFFE asked the Minister of Health whether his attention had been called to the number of cases in which insured persons lost the entire amount of their contributions over a long period of years owing to the fact that shortly before attaining the age of 65 they started some small business of their own; and whether, when they ceased to be insured employees, their approved societies notified them that they could preserve their rights by continuing as voluntary contributors.—Mr. SHAKESPEARE replied: My right hon. friend is aware that every half-year a number of persons, after having been insured for a period of years as employed contributors, take up business on their own account, and after a free period of insurance of about 21 months can only retain their rights under the schemes of health insurance and contributory pensions by becoming voluntary contributors. Approved societies have been instructed to inform their members of the position, and my right hon. friend has no reason to think that they fail to do so.

MIDDLESEX HOSPITAL.—The new buildings of Middlesex Hospital are to be opened by the Duke of York on May 29th. He will be accompanied by the Duchess.

KENT AND SUSSEX HOSPITAL.—Criticism which had been levelled against the governors of the Kent and Sussex Hospital, Tunbridge Wells, in spending a sum of £188,422—£200,000 was the original approximate figure—on the erection of a new building on the Great Culverden site, was largely dispelled at the first annual meeting held at the hospital on March 21st. Incorporated in the new building are the Tunbridge Wells General Hospital, the parent institution founded 107 years ago, the Eye and Ear Hospital, and the Kent and Sussex Hospital, and as a whole is now known as the Kent and Sussex Hospital. The building has accommodation for 204 patients, and recently no fewer than 202 beds were in occupation on one day, giving an answer to the suggestion that the governors were not justified in providing for such a number. Furthermore, there is accommodation for 18 private patients, and as many as 14 have already been occupied at one time. Naturally, with the occupation of a new hospital, expenditure had been heavy, and equipment cost more than had been estimated, but the amount in excess of income was met by a number of legacies. The building fund marked an overdraft at the bank of £23,000, but there were the proceeds of the sale of the old General Hospital and site still to be realised.

drugs. This point is one of many that calls for consideration in determining the relationship between man's two trypanosomes. At the moment, the two main views on this problem are either that *T. rhodesiense* is a variant of *T. gambiense*, or that it is a *T. brucei* that is pathogenic to man. The matter is still unsettled. According to the latter view, *T. gambiense* in its typical "human" form, in the course of ages and among several other changes from the *brucei* type, may have acquired sensitiveness to arsenic, a peculiarity which it readily loses again.

It should be remembered that no one, so far as is revealed by the literature at my disposal at the moment of writing, has yet succeeded in preparing from a *T. gambiense* really sensitive to arsenic a strain resistant to arsenic that at the same time retains its transmissibility by tsetse. It is a pity to lose sight altogether of this aspect of the phenomenon of arsenic resistance, academic though it may be, and automatically to ascribe any resistance possessed by *T. gambiense* when first isolated from man to previous contact with arsenical drugs.

I am, Sir, yours faithfully,
H. LYNDHURST DUKE.

Human Trypanosomiasis Institute, Uganda, March 5th.

ERGOMETRINE

To the Editor of THE LANCET

SIR,—The interest aroused by the recent announcement of the discovery of the new water-soluble alkaloid of ergot (ergometrine) by Dudley and Chassar Moir will probably have made some obstetricians wishful to try the clinical use of a substance of such high promise.

By the application of the published details of the methods employed by the above-mentioned workers, the scientific staff of this company has already prepared some ergometrine with a view to its production on an industrial scale; and I write to state that a sample tube of tablets each containing 0·5 mg. of ergometrine will be sent without charge to any obstetrician who applies.

I am, Sir, yours faithfully,
CHARLES ALEX. HILL,
Chairman and Managing Director,
The British Drug Houses Ltd.

Graham-street, N., April 1st.

PHYSICAL CULTURE FOR MENTAL PATIENTS

To the Editor of THE LANCET

SIR,—In your issue of Feb. 16th (p. 407) you reported a discussion introduced by Lord Kilmaine in the House of Lords on physical culture for mental patients. For some years physical culture has formed part of the treatment at this hospital, which to-day possesses an up-to-date gymnasium, the equipment of which includes, among other things, parallel bars, bridge ladders, Roman rings, trapeze, rope ladders, rowing machines, pulley weights, punching ball and sack, Terry's chest expanders, auxiliary expanders and developers, and Sandow's spring dumb-bells. Every morning from 7 to 7.30 all the younger patients, male and female, attend the gymnasium for massed physical exercises under a qualified instructor. This is followed by community singing for half an hour. From 8.30 till 11.30 A.M. batches of patients leave the occupational therapy department to attend the gymnasium for half-hourly periods, when specialised physical culture is studied. At these classes the patients show keen coöperation. The subjects included in the special classes are Indian club swinging, diving and vaulting over a human horse, skipping, boxing, dumb-bell exercises, human pyramids, fencing (with wooden swords), living statuary, acrobatic stunts, Jiu-jitsu, wrestling, and tableaux. A high standard of efficiency is reached and at all the hospital concerts at least two turns by the physical culture classes are included in the programme.

I am, Sir, yours faithfully,
MOORE TAYLOR,
Major, I.M.S.

Ranchi European Mental Hospital, Bihar and Orissa, India, March 13th.

CANNABIS INDICA

To the Editor of THE LANCET

SIR,—Will you allow me to correct an inaccuracy which occurs in an article describing a case of cannabis indica intoxication in your last issue. Dr. Baker-Bates states (p. 811) "there is no law against the possession of or smoking of the plant." This is not the case. The Coca Leaves and Indian Hemp Regulations, 1928 (S.R. & O. 1928, No. 982), apply to Indian hemp the provisions of the Raw Opium Regulations, 1921 (S.R. & O. 1921, No. 864), and it is accordingly an offence for any person (unless he is licensed or otherwise authorised to do so) to be in possession of or attempt to obtain possession of Indian hemp.

I am, Sir, yours faithfully,
WM. H. COLES,
Chief Inspector under the Dangerous Drugs Acts.

Home Office, Whitehall, April 9th.

STERILITY FOLLOWING SYMPATHECTOMY

To the Editor of THE LANCET

SIR,—In his valuable paper in THE LANCET of April 6th Dr. Arthur Hurst stresses the frequency with which sterility follows sympathectomy in male patients, and reports two cases where marked neurosis resulted from failure to warn the patient before operation of this disability. But, in suggesting that similar sex complications may occur in women, Dr. Hurst makes a statement that cannot remain unchallenged. He states that "as most of the females upon whom the operation" (i.e., presacral neurectomy) "has hitherto been performed have been elderly women in whom the sexual functions are already in abeyance, it is still possible that these functions may be seriously impaired if the operation is performed in girls and young women."

Both the fact and the corollary contained in this statement are curiously incorrect. The operation was originally designed for the relief of dysmenorrhœa and this disorder still remains its predominant indication. Consequently, most of the patients have been girls or young women: for example, the average age in my own series, which include several cases of carcinoma of the cervix and late pelvic neuralgia, is 28, and Cotte's larger series gives a similar figure. All these cases have now been observed for some years, several of them through subsequent pregnancies, and in not a single one has there been noticed any aberration of the sexual function (with the exception of some increase in sex feeling). Coitus, conception, pregnancy, and parturition remain unaffected by the operation, and there are no untoward effects on either bladder or rectum.

Cases of true intractable dysmenorrhœa, by which I mean those in which all medical and minor surgical treatments have failed to relieve, are admittedly uncommon, but it is in these very cases that sympathectomy is so brilliantly successful; it is therefore particularly unfortunate that a physician of Dr. Hurst's eminence and authority should propagate such a damaging misconception of the possible sequelæ of this operation. I entirely agree with him that sympathectomies are performed too often and with too little justification; but I must again emphasise the fact that resection of the presacral nerve in women, when properly performed for proper indications, has no deleterious effect on the sex functions, including that of conception, and is generally productive of nothing but good results.—I am, Sir, yours faithfully,

Harley-street, W., April 9th. A. A. DAVIS.

SIR JOHN ROSE BRADFORD

To the Editor of THE LANCET

SIR,—The obituary notice in the *Times*, contributed by Sir Humphry Rolleston, reminds me of an interesting piece of prophecy in which Bradford and Rolleston were associated. Somewhere about 1895—40 years ago—I was sub-editing the *Practitioner* and had designed a "monthly review of the medical sciences," in which a special department was reviewed each month by one of the rising young physicians of those days. Bradford was responsible for Diseases of the Kidneys and Rolleston for Diseases of the Digestive Tract. One morning they were both in my waiting-room, where they met the late Dr. Michael Foster, an old friend of mine from San Remo and Harrogate. He came into my study first and said, "I won't keep you long as you have two men in the waiting-room whom I know. Mark my words—they are both future presidents of the Royal College of Physicians." Sir Humphry Rolleston was elected president in 1922, and Sir John Rose Bradford succeeded him in 1926.

Bradford was an excellent organiser of congresses. The tercentenary celebration of the publication of Harvey's "De motu cordis" was primarily, if not entirely, a College affair and was a great success. When the centenary of the birth of Lister came round in 1927 it was felt that King's College, University College, London University, the Royal College of Surgeons, and the Universities of Edinburgh and Glasgow were all justified in celebrating their association with the great master. But Bradford had the wise idea of proposing that the Royal Society, of which Lister had been president, was the body to take chief charge of the event. With him as chairman of the executive committee, and Sir Henry Dale as secretary, we remember what a brilliant affair the celebration was. On both these occasions—the publication of Harvey's great work and the birth of Lister—Bradford's wise imagination and excellent conduct added to the reputation of the Royal College which he served so well.

I am, Sir, yours faithfully,

April 9th. ST.C. T.

STRICKLAND GOODALL MEMORIAL

SUGGESTIONS for a memorial to the late Dr. Strickland Goodall reach us in the following communication:—

"Dr. Joseph Strickland Goodall died towards the end of last year at the early age of 59. His memory is revered by many who benefited not only by his skill but also by his great capacity for friendship and by his ungrudging and willing service. He was a man with a large and generous mind. It is therefore desired to perpetuate his memory, and we feel sure that there must be many among his professional colleagues, friends, and patients who would wish to coöperate with us. We are of the opinion that the form of memorial he would have preferred would be a lectureship and medal named after him. This lecture would embrace cardiology in its widest sense. Dr. Strickland Goodall was an examiner for the Society of Apothecaries for many years, and in view of his close association with the company we think it appropriate that the lectureship and medal should be under its auspices. The court of assistants has graciously consented to act as trustee. We should be glad if all those who feel they would like to participate would send their contributions to the treasurer, Strickland Goodall Fund, Westminster Bank, Harley-street, W.1."

The signatories are: Viscountess St. Cyres, Sir Leicester Harmsworth, Sir James Berry, Charles Carpenter, D.Sc., Mr. John Cohen (chairman of the National Heart Hospital), Prof. A. W. Sheen, Prof. J. W. Eyre, Mr. George Joseph, Dr. Russell Reynolds, Dr. Evan Bedford, Mr. Bertram Mendleson, Mr. Lambert Rogers, Dr. Maude Richards, and Dr. Jenner Hoskin.

BRITISH EMPIRE CANCER CAMPAIGN

Lord Reading presided at a meeting of the grand council of the Campaign held in London on Monday last. A grant at the rate of £350 per annum for the year 1935 was made to Sir Leonard Hill for the services of Dr. T. Reiter whilst continuing his research work on short-wave therapy in the laboratories of the St. John Clinic and Institute of Physical Medicine. A grant of £1000 per annum for two years was made to the North of England council of the Campaign, to be placed at the disposal of Prof. W. E. Curtis, of the Armstrong College, Newcastle, and Mr. F. Dickens, D.Sc., research director of the Cancer Research Institute of the North of England council, for conducting an exhaustive scheme of research in short-wave therapy. It was reported that the scientific advisory committee of the Campaign attaches much importance to this research. Further, a grant of £700 was placed at the disposal of the scientific advisory committee for a special investigation of the biological reactions of monochromatic radiations of various wave-lengths.

The grand council adopted the recommendation of its committees that it was desirable to continue to offer from time to time a prize and medal for the best essay submitted on a set subject concerning cancer research. It was decided also that the Campaign should award gold medals from time to time to those in the British Empire who had carried out and published contributions to cancer research of outstanding merit. As a result of representations by members of the provincial branches, the council has established a central propaganda committee. One of its objects will be to issue information which will enlighten the public generally about the onset of cancer, with a view to inducing sufferers to seek medical advice at the earliest possible moment.

It was reported that a largely increased number of centres have undertaken, in the present Jubilee year, to organise collections throughout the country. In the provinces May 25th has been selected for the majority of the 1700 collections, while in London July 9th has been allotted as the flag day for the metropolitan and city areas.

HOVE GENERAL HOSPITAL.—At the annual meeting of the governors on March 26th it was announced that the King's Jubilee will be commemorated by building a Jubilee wing. It will form part of an extension scheme now nearing completion, and will bring the number up of beds from 22 to 50, thus serving the hospital being recognised by the General Nursing Council as a complete training school for nurses. The Mayor of Hove, who presided over the meeting, mentioned that the cost, added to the sum already spent in the extension ward now being carried out, would bring the total sum involved to nearly £34,000. About £20,000 remained to be raised.

OBITUARY

SIR JOHN ROSE BRADFORD, Bt., K.C.M.G., M.D., F.R.C.P.Lond., F.R.S.

LATE PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

THE death occurred on Sunday last, April 7th, of Sir John Rose Bradford, distinguished physiologist and physician, and indefatigable worker in many important directions of scientific and medical organisation. He died, after a somewhat prolonged illness, in the house in Manchester-square, London, which he had occupied nearly the whole of his professional life. The event occurring a few days after the death of Sharpey-Schafer, his senior by some 12 years, must remind us how these two great men, though absolutely differing in career and performance, stood out as pioneers of the now generally accepted view that all scientific research which is allied to or ancillary to medicine should be brought into association with clinical practice. It was this great ideal in all Rose Bradford's work that made him accepted universally as a leader of the medical profession of particular distinction.

[Photograph by Elliott and Fry

SIR JOHN ROSE BRADFORD

John Rose Bradford was born in London in 1863, the son of Abraham Rose Bradford, Deputy Inspector-General of Hospitals, R.N., by Ellen, daughter of Nicholas Littleton of Saltash. He was educated at a school in France and at University College school and the medical school of University College Hospital, where he entered as a student in 1882, when the staff comprised such notable men as William Jenner, Russell Reynolds, Bastian, Schafer, Gowers, Ringer, and Marcus Beck, the last two of whom were Bradford's particular heroes. He graduated as B.Sc. Lond. in 1883 and as M.B. in 1888, proceeding in the same year to the D.Sc. and in 1889 to the M.D. degree, when he obtained the gold medal for medicine. In 1892 he took the diploma of M.R.C.P. Lond. and was elected F.R.C.P. five years later. He served the house appointments, and was for a time demonstrator of anatomy in the school. In 1890 he became assistant physician to the hospital and was shortly after elected to the same position at the National Hospital, Queen-square, while he served for a period on the staff of the Seamen's Hospital, Greenwich.

Such was the extended clinical field open to Bradford from the start, but he had made a great mark in physiological work before obtaining his first medical degree. He published physiological papers with Bayliss on the electrical phenomena accompanying secretion in 1885 in the *Proceedings* of the Royal Society, and these were followed by contributions to the *Journal of Physiology* on the innervation of the renal blood-vessels and on the action of certain drugs on the kidney. Between 1889 and 1892 he contributed to the *Proceedings* of the Royal Society papers on the innervation of the pulmonary blood-vessels in association with H. P. Dean, and with Bayliss on the innervation of the vessels of the limbs, and in the latter year he wrote in the *Journal of Physiology* a paper on partial nephrectomy and the influence of the kidney on metabolism, while he contributed to the Royal Society a preliminary note on the effect on nitrogenous metabolism of removing portions of the kidney. In recognition of the quality of these researches he was elected F.R.S. in 1894, at an unusually early age.

In 1895 Bradford was elected superintendent of the Brown Institution, where he continued his physiological investigations. He held this post for eight years, and at the beginning of his long association with the Royal College of Physicians he recorded his experiences thereat. For when he was, in 1897, appointed Goulstonian lecturer at the College he took as his subject the pathology of the kidney, and the lectures were founded on work done at the laboratory of the Brown Institution. He traced the results of partial and complete nephrectomies on the general metabolism of the body, and on the composition of the urine, describing in conclusion the phenomena of uræmia as seen clinically. The lectures illustrated his invariable attitude towards the problems of scientific research—any lessons to be learnt from them should be interpreted for the medical profession from the clinical aspect. He had already published an excellent little textbook, entitled "Clinical Lectures on the Urine"; the lectures had appeared in serial form in the *Clinical Journal* and while covering the ground with great clearness and accuracy, brought Bradford's laboratory work actually to the bedside. Indeed all Bradford's contributions to medical literature showed this practical bent. He wrote the articles in Allbutt's "System of Medicine" on the General Pathology of the Renal Functions and on Nephritis, and in Allchin's "Manual of Medicine" those on Rabies, the Mycoses, and Diseases of Ductless Glands. The essays were in each case simple and practical, the results of personal investigations being collated with those of clinical experience, the author's own, and that of much trustworthy authority.

In 1897 Bradford became full physician at University College Hospital, and professor, first of materia medica and later of clinical medicine. In private practice he displayed his great qualities, using a wide range of knowledge and never allowing theoretical considerations to sway practical judgment. His original mind was displayed in clinical medicine as it had been in physiology; and he became a great clinical teacher because his interpretation of the facts of a case was accurate and his presentation of them clear and ordered. He commenced unfolding a case commonly by a few tactful questions asked of a clinical clerk, and the case was finally displayed in a wonderful way, the essential points standing out clearly against a background of less important details. At such times diagnosis seemed very simple and self-evident. Honesty was an essential part of his nature, and strict adherence to the track, as he saw it, characteristic of his discourses, since he taught what he saw in the patient and freely illustrated his statements by reference to cases which had come under his own personal observation. Orderliness and clearness of thought, originality in classification into clinical types, sound judgment, and avoidance of irrelevance were thus characteristic of his teaching. His memory was very retentive and the facts of medicine so precisely and clearly arranged in his mind that he had no need of notes to aid him; in fact he used to say that looking at notes worried him, and when lecturing at University College he went through the whole of medicine without a note of any kind.

His labours in the field of experimental physiology were discontinued after 1899, and his time was fully occupied, apart from work in the wards or the consulting-room, by the numerous public duties which he undertook. At the Royal Society he was foreign secretary in 1907–1908 and secretary from 1908–1915, his full term of office not being completed owing to his appointment in 1915 as a consulting physician to the army with the B.E.F. During his secretaryship there were organised by the Society on behalf of the Government special commissions on Mediterranean fever and on sleeping sickness, with the activities of which he was closely concerned. His services were in constant demand as an examiner, a post for which he was so excellently fitted, and in this capacity he acted for the University of London, the English Conjoint Board, and the Indian Medical Service.

At the Royal College of Physicians of London he played a prominent part from the day of his election as a Fellow and his selection as Goulstonian lecturer. He was Croonian lecturer in 1904, Lumleian lecturer in 1920, and Harveian Orator in 1926, the year of his election to the presidency of the College. He served this office for five years and was an admirable president, exercising his gifts of accuracy, retentive memory, and fairness to the appreciation of everyone. The tercentenary celebrations in honour of Harvey occurred during his term of office and were carried through with great success. Reference has already been made to his Goulstonian lectures, and in his subsequent addresses he displayed the same general wisdom and special accomplishment, maintaining in these deliveries his great ideal that research should have for its object the advance of clinical medicine. In the Croonian lectures on Bright's Disease and its Varieties, there was a certain sequence to the Goulstonians, especially when the lecturer was discussing the excretory activities of the kidney. Bradford, the most fair and courteous of opponents, could be emphatic when emphasis was needed, and he always felt that it was needed when protesting against interference with the work of research by prejudiced observers. In these lectures he took occasion to emphasise the similarity that had been found to exist between experimental results and the processes seen in the human subject as a result of renal disease, thus justifying the prosecution of experimental inquiry. In the Lumleian lectures, delivered after the war, Bradford narrated his clinical experiences during the war, when with the rank of major-general and as consulting physician to the B.E.F. he was present throughout the campaign in France and Flanders. After useful reflections upon problems in connexion with wastage, due or partly due to battle casualties, he dwelt on the occurrence in the armies of nephritis and polyneuritis and on the result of gunshot wounds of the chest. In the Harveian Oration, delivered just before his election as president of the College, he expounded eloquently the debt which medicine owes to the experimental methods introduced by Harvey. Harvey's greatness he found to be shown by the fact that, notwithstanding the conditions prevalent in his time, he was able so to free himself from the traditions of the past, and from the influence of authority and dogma, as to lay the foundations of modern science by his insistence on the fundamental importance of experiment and of accuracy of observation. This series of lectures, ranging over more than a quarter of a century, demonstrated Bradford's persistent point of view, that only through intensive inquiry, relentless scrutiny of findings, and testing of theories can advances be brought about.

Bradford, until shortly before his death, was senior medical adviser to the Colonial Office. He was also extremely well posted in all the problems, social, charitable, and material, comprised in the organisation of the voluntary hospitals. And his long connexion with the King Edward Hospital Fund for London formed another call upon time which seemed ever inexhaustible. He was chairman up to a few days before his death of the executive committee of University College, and his interest in University College Hospital was maintained in the most intimate way until the end of his life.

But those who may have regarded Bradford either as an unbending man of science or a distinguished official would be surprised to know how complete his familiarity was with the conduct of medical practice and with the material and ethical difficulties arising in connexion with it. He was for many years president of the London and Counties Medical Protection Society. He presided regularly at the meetings of the Society and entered carefully into the claims of all contending parties, and although his ideals of professional behaviour were very high he was sympathetic with those whom ignorance or indiscretion had placed in a difficult position, and leaned to the side of mercy in his judgments.

Bradford was appointed K.C.M.G. in 1911, was made C.B. and C.B.E. at the termination of the war, and in 1931 was created a baronet. He was a corresponding member of American and French medical societies and received honorary degrees in science, medicine, and law in the universities of Cambridge, Edinburgh, Dublin, Durham, and Christiana. Never was recognition more fully merited.

Sir John Rose Bradford married, in 1899, Mary, daughter of the late Thomas Ffoulkes Roberts, J.P., and niece of the well-known physician and authority on renal disease, Sir William Roberts. There were no children of the marriage. Lady Bradford followed her husband abroad almost immediately after he was appointed consulting physician to the B.E.F., and then became an unofficial letter-writer for the sick and wounded. What beautiful work she did she has narrated in an unassuming little book "A Hospital Letter-writer in France," from which it can be gathered that in communicating with the relatives of the wounded soldiers she did much more than send greetings from the patients to their friends, but included an accurate medical report of the condition of the patients at the time of writing. The sympathy of all will go out to Lady Bradford in her great loss.

Sir Thomas Barlow writes: "By the death of Sir John Rose Bradford, London has lost one of its worthiest physicians and ablest teachers of the science of medicine. I first got to know him when he came 'across the way' from University College to the Hospital. He soon gained the esteem of his teachers by his quick apprehension of [illegible] rpretation of physical signs [illegible] ac [illegible] his reports. He was an admirable house physician, always enthusiastic and alike indefatigable in ward, casualty and post-mortem room in carrying out the instructions of his chief, Dr. Ringer.

"It was during this period that Bradford made some noteworthy investigations on acute severe pernicious anæmia. He will, of course, be specially remembered by his researches on the functions of the kidneys and notably in relation to the removal of varying amounts of kidney substance. He himself considered that his best research work was concerned with electrical changes in salivary gland and other gland secretions, and collateral to these must be placed his investigation on the vaso-motor nerves of kidneys, lungs and limbs. It should also be mentioned that, stimulated by his friend, Sir Michael Foster, he worked out some important points in the anatomy of the trypanosomes of sleeping sickness.

"Early in his career Bradford was awarded a scholarship by the Grocers' Company for original scientific research. His relations with the Company were always most cordial, and later in life he was appointed their adviser on grants to be made for science research. He was elected assistant physician to U.C.H. at the early age of 26, and in due course full physician, and was appointed successively professor of materia medica and therapeutics, professor of systematic medicine and lecturer on clinical medicine. Both as lecturer and as clinical teacher, Bradford was lucid and terse, and developed his expositions on a scientific basis. He had an accurate and well-trained clinical memory and was able to recall details of patients' symptoms in a way which astonished his auditors. He established a warm personal relationship with his students and especially with his house physicians and clinical clerks, with many of whom he retained an abiding friendship till the end of his life.

"To those who met him casually, or only officially, Bradford's manner, in his younger days, though courteous, appeared somewhat cold and reserved. He found it difficult to maintain even an outward semblance of friendliness to those who fell short of his own fine standard of mental and moral integrity, but with riper years he became, not less shrewd in judgment, but less trenchant in criticism. This occasional austerity of manner disguised a very tender heart, and anyone in pain or trouble could be sure of enlisting his unremitting sympathy and help, as was evidenced by the readiness with which his colleagues, former students and nurses appealed to him for counsel when they or their belongings fell ill.

"His friendships, both with men and women, were an important element in his life, and in the company of those whom he really knew, whether at home or in travel, or when entertaining his shooting friends at Bryn, he gave rein to his bantering but kindly humour, and was truly the good companion.

"He had many interests outside his profession, and was a keen traveller, though his activities in that direction were limited by his sense of duty to his wife's estate and the welfare of the tenants. He was a good ornithologist, had a sound working knowledge of marine zoology, and was an interested Fellow of the Zoological Society. His married life was exceedly happy, and Lady Bradford, herself an able botanist, was a perfect comrade, both in his working life and in times of leisure.

"Bradford's patience and fortitude during his last illness were beyond praise. His integrity, his devotion to duty and his courage recalled the virtues of the Roman Stoic, but his kindliness, his love of fair play and his generous appreciation of other people's good work were characteristic of the English Christian gentleman, and his genius of friendship will always keep his memory green among those who loved him and worked with him."

WALTER GAWEN KING, C.I.E., M.B., C.M. Aberd.

LATE SANITARY COMMISSIONER OF MADRAS AND BURMA

Colonel Walter King, I.M.S., who died in London on April 4th in his 84th year, occupied a position so important in Indian preventive medicine that he has been styled the father of public health in India, and his claim to the title was a substantial one.

Walter Gawen King, the son of the late Mr. J. H. King, of Kineton, near Warwick, received his medical education at the University of Aberdeen. He graduated there in 1873, and immediately entered the Indian Medical Service. He served first with the 5th Burmah Regiment, now the 90th Punjabis, and then as a civil surgeon filled a long series of important posts in Madras. He was professor of physics in the Presidency College, and of hygiene in the Madras Medical College, special sanitary officer to the city, superintendent of the government lunatic asylum, and inspector of vaccination. In 1894 he was appointed sanitary commissioner to the government of Madras, a post which he filled for 11 years. While in Madras he received the special thanks of the government for services rendered during the famines of 1876–77 and 1896–97, and in 1903 the government named after him its provincial laboratories, the King Institute of Preventive Medicine. In 1906 he became sanitary commissioner of Burma, and was for four years inspector-general of civil hospitals in Burma. During the war he acted as assistant director of medical services, A.M.S. to the Western command, and received the commendations of the Secretary of State for War for his valuable services.

King was undoubtedly one of the greatest of the members of the I.M.S. He was the first to insist on the necessity for separate departments of public health in the Indian provinces, and it is largely due to his powerful advocacy that the sanitary commissioners, now known as directors of public health, acquired positions of independence—previously they had been subordinate to the administrative officers of the provinces.

Colonel R. H. Elliott sends us the following outspoken comment on the position King won and maintained so well. "When," he writes, "in 1895 I first met King he was newly installed sanitary commissioner to the government of Madras, and the position was a difficult one because sanitation was by this appointment taken away from the control of the surgeon-general of the government of Madras and made a more independent appointment. King now fell directly under the government, and was independent of the surgeon-general. District medical officers in India had been formerly not only responsible for the supervision of the hospitals, but also for the sanitation of their districts. In the former capacity they were subordinate to the surgeon-general and in the latter to the district commissioner. The arrangement had worked well in old and sleepy days when sanitation was looked on somewhat as a fad. King's appointment upset all past ideas. He was obviously determined to do something, and a big something at that, for the people submitted to his care. The control of small-pox, of cholera, and of other diseases incidental to the movement of crowds during religious festivals was to King a live issue, the tackling of which in a practical manner was bound to bring great results in its train. There was an inevitable clash of personalities under the transference of responsibilities, and King went straight ahead and with the virtues of an enthusiast was regardless of consequences. Such was his vital force and so sound and true were his ideas that despite difficulties he won through. He knew what he wanted, and he was determined to get it." Colonel Elliott adds, "Not long ago he sent for me, being convinced he was getting glaucoma; characteristically he faced the worst and asked to be told the truth. King never was a clinical man, and his diagnosis was quite mistaken. When I saw him, old, broken in health, and bedridden, he was controlled by the courage of his early days. India owes Walter Gawen King a debt which it can never repay."

Colonel H. H. King, late superintendent of the King Institute of Preventive Medicine at Guindy, Madras, writes: "The institute perpetuates King's name and his devotion to public health. It was set up by the Madras government in 1903 in response to his wishes when sanitary commissioner of the presidency. It started as a vaccine lymph depôt, but gradually increased its activities and now covers a wider field than any other laboratory in India. It serves the whole presidency as a manufactory not only for vaccine lymph, but also for all bacterial vaccines except plague, both preventive and therapeutic. It is in addition the chief bacteriological laboratory in the presidency, and the only public health one, in which latter capacity it includes the work of public analysis under the Foods and Drugs Act. Finally, it is a research laboratory from both clinical and public health aspects, and I stress its many-sidedness because to have all these activities centred in one place gives Madras the advantages of concentration and economy in administration. The extent of the work has grown enormously, and though this expansion has occurred mainly since Colonel King's time, the government of Madras will ever remain indebted to him for his energy as founder. As I have recently been director of the institute, I may be permitted, as representing it, to offer the sincere condolences of myself and of the whole staff of the institute to Colonel King's family—their loss is ours, and indeed that of all India."

These tributes to the work and the personality of Colonel W. G. King illustrate the force for good of the man, and make us understand how those actually engaged in sanitary administration in India regarded him with such esteem.

JOSEPH SHARDLOW, M.B., M.R.C.S.

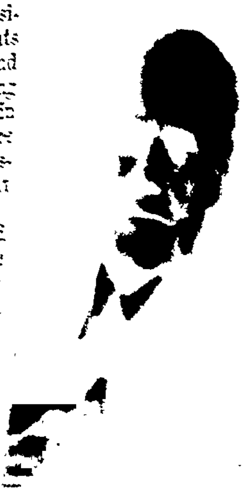
THE death of Dr. Shardlow, who was over 30 [illegible] on the honorary staff of the Sussex Mat[illegible] Hospital, occurred on April 1st after a long [illegible] The severance of his many connexions, professional and public, with Brighton life makes his death [illegible] as a public loss. He received his medical [illegible] at University College Hospital, took the [illegible] double diploma in 1896, and graduated as M.B. [illegible] in the following year. He was a successful [illegible] was house physician at his hospital and a dem[illegible] in physiology in the medical school, and was [illegible] time resident medical officer at the Eas[illegible] Hospital for Children. At the close of this [illegible] he entered medical practice in Brighton [illegible] the beginning made maternity work a [illegible] 1902 he was elected to the staff of the Sussex [illegible] Hospital, a position which he held [illegible] being for the last ten years the senior [illegible] staff. He was also one of the medical [illegible] Brighton and Hove Dispensary, where [illegible]

office was nearly as long as at the Sussex Maternity Hospital. He was medical officer for the Southern Railway, and in connexion with this post he received a presentation clock on behalf of the Southern Railway ambulance class. He was a frequent lecturer on behalf of the St. John Ambulance Brigade, and for many years acted as an examiner for the police. Dr. Shardlow was unmarried, and died in his 64th year.

SIR JOHN COLLIE, C.M.G., M.D. Aberd.

CONSULTING PHYSICIAN TO THE MINISTRY OF [illegible]

Sir John Collie, who died at his home in Por[illegible] terrace on April 4th at the age of 74, was [illegible] recognised as the most distinguished inves[illegible] cases of suspected malingering. But he [illegible] more than this; he put medico-legal pr[illegible] sound basis of experience.



Robert John Collie was the fourth son of [illegible] Collie, advocate, of Pitfodles, Co. Aberdeen [illegible] to school and college at Aberdeen, stud[illegible] there and at Edinburgh [illegible] qualified in 1882, taking the M.D. Aberd. [illegible] qualifying he spent some time in resident appointments at Edinburgh and Sunderland, staying on for six years in private practice among the industrial population at the latter place.

When he decided to try his fortune in London, he at once began to undertake work of a public character. In [illegible] he became associated with the London School Board as medical [illegible] [illegible]

on malingering which first appeared in 1913 and was further elaborated in 1917, when an important chapter appeared on the "Return to Work," in which Collie emphasised not only the desire to shirk but the unwisdom of reinstating a man on wages he is not yet capable of earning. In many cases, he would say, the right answer to "Is A.B. a malingerer?" is "A.B. is really physically fit, but he requires that push towards usefulness which many men off work require. He has not any real incapacity, but he has a feeling of inability caused by nervousness, all of which could be overcome by work. He is brooding over his recent injury, and the compensation he is receiving takes away the stimulus to work. Half wages mean semi-starvation, and have a bad physical and moral effect."

Collie's share in framing the Workmen's Compensation Acts was one of his outstanding merits. He assisted the departmental committee in deciding the regulations for industrial diseases in the Act of 1906. He took the view that a medical assessor should be present in all cases where medical evidence was to be given about facts in dispute, and he obtained insertion in the Bill of 1923 of a clause giving either party the right to claim that a case should go before a medical referee.

Some idea of the extent of Collie's experience of occupational fitness may be gathered from a report, issued just before the war, on 31,000 consecutive medical examinations over a period of nine years, nearly half of which were made on candidates for employment. It was natural that he should be nominated by the Government on the advisory committee for the National Insurance Act of 1911, and although he only held the position for a year or so, it awakened an interest in the problems of insurance practice which he never lost. It would be tedious to enumerate the other bodies which used his services at this time in medical examination —assurance societies, shipping federations, or metropolitan police divisions; he was medical referee for the borough of Finsbury, a member of the Insurance Committee for London, and Home Office referee under the Workmen's Compensation Act. It could not be expected that medical mistakes were never made, but they were very exceptional, and Collie's skilled work for metropolitan authorities must in the aggregate have saved vast sums of money in wages, while rescuing multitudes of patients from the ill-effects of unnecessarily protracted invalidism. In 1908 he was put on the commission of peace, and in 1912 he was knighted. The war found him congenial occupation. He became a major, with temporary rank of colonel, in the R.A.M.C., and president of a special medical board for nervous disorders. He was one of the first to recognise that the emotional suppression cultivated by every good soldier predisposes to nervous strain, and he was as active in finding homes of recovery and suitable light occupation for shell-shocked men as in arranging immediate psychotherapeutic treatment behind the lines. For this service he was made C.M.G., and appointed director of medical services to the Ministry of Pensions.

Of Sir John Collie's personal qualities he has made it easier to write by saying of himself: "I have never been in the position of the man of whom everyone speaks well—few men have been so constantly abused for so long a time." This was, he thought, the inevitable result of conscientious performance of duties such as his. The feeling was no doubt accentuated by the fact that he was generally on the side of the angels and did not often represent what might be called the under-dog. A personal friend writes: "It would, perhaps, be not quite correct to describe Collie as a typical Aberdonian Scot, but he had a dogged honesty of mind and a contempt for humbug. He was courageous and fearless. A certain combativeness made him a 'bonnie fechter'; but this also made him somewhat heedless at times of the effects of his actions. His special subject made him a close student of human nature, especially that of the working man. This brought him much into contact with chicanery and fraud, but he had real sympathy for the genuine sick and a kindly eye for the man who honestly wanted to get back to work. He told me, however, that, for all his experience, he often found the mentality of the artisan difficult to fathom. Although he entered Parliament for a Glasgow division, I doubt whether politics really attracted him. He had a simplicity of outlook upon public affairs which contrasted strangely with his acknowledged shrewdness in his special métier."

All his life Collie had an urge to write. He had a lucid and unaffected style, and a vigorous and incisive way of making his point. Early in his life he collaborated with Dr. J. D. C. Mortimer in a book on "Nursing at Home," and with Dr. F. C. Wightman in little handbooks on "First Aid to the Injured and Hygiene and Health." Later he wrote (apart from malingering) on medical evidence and the law of compensation. A year or two ago, as chairman of the Paddington health committee, he brought out a report on infant mortality in the borough which contained evidence of skilled investigation. Quite recently he induced a team of writers to make up a volume on "Recent Progress in Medicine and Surgery."

Sir John Collie was twice married. In 1886 he married Jessie, daughter of John Edgar, of Locharwoods, Dumfriesshire, and after her death in 1928 he married Lady Arrol, daughter of Mr. James Robertson and widow of Sir William Arrol. He leaves a son, Arnold Edgar, who is qualified to practise both law and medicine.

MR. SHEPHERD DAWSON, D.Sc., who died on March 27th, was consulting psychologist to the Royal Hospital for Sick Children, Glasgow. Dr. Dawson held a prominent position amongst psychologists, having been chosen to occupy the position of president of the psychology section of the British Association at the Aberdeen meeting in 1934. His address on that occasion was reviewed in our columns at the time. Although not himself a member of the medical profession he was familiar with the study of psychological problems associated with disease in childhood, and for many years he investigated the effect of pathological processes on the intellect. The results of this investigation were embodied in a series of papers which appeared in the Archives of Disease in Childhood, and in a special report to the Medical Research Council. Last year he was invited to address the Royal Medico-Chirurgical Society of Glasgow on Disease and Intellect. He was something of an authority on the use of the statistical method, and his book "An Introduction to the Computation of Statistics" has proved of great help to workers in this field. A man of charming personality, ever ready to be of assistance, his early death is a serious loss to his colleagues, whose sympathy goes out to his widow and daughter.

MEDICAL NEWS

University of Aberdeen

On April 3rd the honorary degree of LL.D was conferred on Lieut.-Colonel A. T. Gage, I.M.S. (retd.), formerly director of the Botanical Survey of India and superintendent of the Royal Botanic Gardens, Calcutta (*in absentia*), and on Prof. J. C. G. Ledingham, F.R.C.P., F.R.S., director of the Lister Institute, London. Other degrees and diplomas were afterwards conferred as follows :—

M.D.—*Hugh Livingston and John MacLeod.
* Commended.

M.B., Ch.B.—G. M. Stephen (first-class honours); W. G. Mackinnon and E. G. G. Rhind (second-class honours); L. F. C. Berlinguet, William Burns, N. J. Craig, W. R. Darnley, Robert Fraser, W. R. Gauld, J. P. B. Gill, Evelyn W. Glennie, S. T. G. Gray, R. W. B. Greig, J. S. Johnstone, A. M. Keith, J. McI. D. McIntosh, Elizabeth Martin, P. L. Masor, William Michie, R. B. Rait, A. I. Ross, J. S. Simmers, R. S. Slessor, Marie S. Sutherland, and Alexander Watt.

D.P.H.—W. F. Gapper and Sheila Thomson.

University of Birmingham

Dr. J. S. M. Connell has been appointed lecturer in applied anatomy, Dr. R. E. Jones lecturer in bacteriology and assistant bacteriologist in the public health laboratory, and Dr. Fritz Jacoby research assistant in tissue culture and assistant lecturer in histology.

Research into Short-wave Therapy

The Medical Research Council have agreed to act as trustees in administering a benefaction of £4000 provided by the Stock Exchange Dramatic and Operatic Society and named in honour of the secretary of the society, Mr. Hugh S. Quekett. The purpose of the gift is the promotion of research into the value of short-wave radiation in the treatment of disease. The money will be used by the Council to meet the cost of assistance and special apparatus in experimental and clinical investigations to be made at the London Hospital under the direction of Prof. D. T. Harris, Dr. E. May, and Sir Robert Stanton Woods.

Welsh Board of Health

Dr. Nancy Gwendoline Howell has been appointed woman medical officer of the Welsh Board of Health. A former student of University College Hospital, she has for three years been assistant medical officer of health for Acton. As the only woman medical officer of the Board she will be especially concerned with maternity and child welfare service.

Liddle Prize at the London Hospital

This prize, which is offered by the college board of the London Hospital under the will of the late Dr. John Liddle every three years, will be awarded in 1936 for the best essay on the relation of pregnancy to diseases of the kidney, excluding infections of the renal tract. Particulars will be found in our advertisement columns.

British Medical Association

Katherine Bishop Harman Prize, 1932.—The Council of the Association will consider an award of this prize, of the value of £75, in the year 1936. The prize is for the encouragement of study and research directed to the diminution and avoidance of the risks to health and life that are liable to arise in pregnancy and child-bearing. Within this sphere competitors are free to select the work they wish to present. All medical practitioners registered in the British Empire are eligible to compete. Should no essay be, in the opinion of the Council, of sufficient merit, no award will be made, but the prize will again be offered in the year following; in this event the money value will be increased. Each essay must be typewritten or printed in English. It must be distinguished by a motto, and accompanied by a sealed envelope marked with the same motto, and enclosing the candidate's name and address. Essays must reach the medical secretary (to whom inquiries may be addressed), British Medical Association House, Tavistock-square, W.C. 1, not later than Dec. 31st, 1935.

Fellowship at University College Hospital

A Bilton Pollard fellowship of £650 per annum is offered to former residents at University College Hospital, London, who hold the diploma of M.R.C.P. Lond., or F.R.C.S. Eng. Particulars will be found in our advertisement columns.

Auxiliary Royal Army Medical Corps Funds

The annual meeting of the members of this society will be held at 5.15 P.M. on Friday, April 26th, at 11, Chandos-street, Cavendish-square, London, W., when the financial statement for last year will be presented and the officers and committee for this year elected.

Studentship at Guy's Hospital

The Astley Cooper studentship, which is tenable at the medical school of Guy's Hospital, becomes vacant in October of this year, and is tenable for three years. Particulars can be had from the secretary to the Astley Cooper trustees at the medical school office, and applications should reach him before May 1st.

East Ham Hospital

There is a debt of £18,000 on this hospital, which was opened six years ago, and until this is cleared off extensions cannot be undertaken. Lord Bethell has offered to give half the sum if the remaining £9000 is raised by the people of the district.

Marie Tempest Ward

A ward for members of the theatrical profession is shortly to be opened at St. George's Hospital. Miss Marie Tempest has asked that the proceeds of her jubilee matinee at Drury-lane theatre on May 28th shall be devoted to this purpose, and the ward is to be named after her.

Poplar Hospital Extension

Lord Reading recently opened the new Bernhard Baron out-patient department of this hospital. The extension has cost £25,000, half of which has been provided by the Bernhard Baron trust.

High Wycombe War Memorial Hospital

This hospital is too small for present needs and will have to be enlarged. It is proposed to double the accommodation by adding a second story and building wards over the existing ones. Of the 800 in-patients treated last year, 475 were members of the contributory scheme.

Stroud General Hospital

The income of this hospital for 1934 was £9389, which is the highest it has ever received. Over £5000 of this was raised by the penny-in-the-pound fund.

Hospital Contributions in Leicester

The Leicester and County Saturday Hospital Society received over £50,000 last year, an increase of over £1200 on the contributions for 1933.

West Suffolk General Hospital

A Jubilee appeal is being made by this hospital for £25,000 to provide a new children's ward and new paying patients' wards.

Royal Victoria Hospital, Dover

This hospital has closed the year with a balance of £33. Two new wards accommodating 20 beds each have been added, and the average cost for each patient has been reduced.

Northamptonshire Mental Institution

Sir Hilton Young, Minister of Health, has opened an extension of the Northamptonshire County Mental Institution at Berry Wood.

Bromley Hospital

This hospital is to have two new wards with balconies, one for men and one for women, which it is estimated will cost £9000. The nurses' home and the massage department will also have to be extended, and a resident medical officer will have to be appointed.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdrs. W. A. Jolliffe to *Cairo*, and as squadron M.O.; L. F. Strugnell to *Barham*; M. B. Macleod to *President* for service inside Admiralty, and as Asst. to M.D.G.; F. C. Wright to *President* for course; and E. Heffernan to *Drake* for R.N. Hospital, Plymouth.

Surg. Comdrs. (D.) J. F. Place to *Pembroke* for R.N.B.; and W. C. Murray to *Victory* for R.N.B.

Surg. Lt.-Comdr. (D.) C. J. Finnigan to *Victory* for R.N.B.

Surg. Lt.-Comdr. J. J. Benson to *Shoreham*.

Surg. Lt.-Comdr. A. M. Pomfret is promoted to rank of Surg. Comdr.

Surg. Lt. A. K. Stevenson to *Exmouth*.

The following have been appointed by the Admiralty as Surgeon Lieutenants for short service: B. R. Alderson, M. Cay, S. C. S. Cooke, D. C. Dobson, J. M. Holford, D. W. Pratt, W. F. Richards, and R. H. A. Turner, and appointed to *Victory* for R.N. Hospital, Haslar, for course of instruction.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. C. Seeley to *Barham*.

Proby. Surg. Sub-Lt. R. T. Gaunt to *Valiant*.

MEDICAL BRANCH GRATUITIES

The Admiralty have made arrangements with the Lord Kitchener National Memorial Fund for the grant of scholarships in aid of the cost of the medical education of the sons of officers and men and ex-officers and men of H.M. Forces, on the condition that holders of these scholarships undertake to enter the Royal Navy as medical officers when qualified to practice medicine and surgery. As the cost of these scholarships is borne by naval funds, the Admiralty consider that they should be authorised to deduct at their discretion the value of the scholarship, in whole or in part, from any gratuity which may be payable to a medical officer who has entered the R.N. in accordance with his undertaking as the holder of one of these scholarships and who fails to complete 15 years' service in the Navy. Authority for this is given in a new Order in Council. No deduction is to be made from the gratuity of a medical officer who is invalided from the naval service for a cause certified by the competent medical authority to be directly attributable to the conditions of his service.

ROYAL ARMY MEDICAL CORPS

Lt. A. J. Clyne to be Capt.

TERRITORIAL ARMY

J. W. E. Webster (late Offr. Cadet, Aberdeen Univ. Contgt. (Med. Unit), Sen. Div., O.T.C.) to be Lt.

ROYAL AIR FORCE

Squadron Leader A. A. Townsend to No. 1 Air Defence Group Headquarters for duty as Medical Officer.

Flight Lt. W. P. Stamm to No. 8 (B) Squadron, Aden.

The undermentioned Flight Lts. are granted permanent commissions in that rank: F. H. Peterson and J. L. Walsh.

Flight Lt. A. H. Barzilay is transferred to the Reserve, Class D.

INDIAN MEDICAL SERVICE

Lt.-Col. D. D. Kamat retires.

Indian Medical Department.—Maj. (Sen. Asst. Surg.) D. A. Gibbon retires.

The Commander-in-Chief has made the following appointments with March dates: Col. R. E. U. Newman, O.B.E., M.C., as Asst. Director of Medical Services for Waziristan District, in place of Col. G. A. D. Harvey, C.M.G., who vacated on March 24th; Maj. N. Cantlie, M.C., R.A.M.C., as Specialist in Surgery, Rawalpindi District; Capt. A. F. Kennedy, R.A.M.C., as Specialist in Surgery, Deccan District; and Capt. A. T. H. Marsden, R.A.M.C., as D.A.D.P., Burma District.

COLONIAL MEDICAL SERVICE

Dr. F. Bell has been appointed Medical Officer, Tanganyika; Dr. L. F. Day becomes Medical Officer, Malayan Medical Service; Dr. F. J. C. Haslam, Director of Medical Services, Northern Rhodesia; Dr. G. H. Henry, Medical Officer, Hong-Kong; and Dr. R. R. Scott, Director of Medical Services, Tanganyika.

DEATHS IN THE SERVICES

The death occured on April 7th at Edinburgh, after a short illness, of Col. George St. Clair Thom, C.B., C.M.G., C.B.E. Born in Madras in February, 1870, the son of George Thom, LL.D., he was educated at Dollar Academy and Edinburgh University, where he graduated M.B. in 1893. He entered the Royal Army Medical Corps in 1894, became Capt. in 1897, Major in 1906, Lt.-Col. in 1915, and Colonel, Army Medical Services, in 1917. He served in the South African War, 1900–1902, was mentioned in despatches and was awarded the Queen's medal with three clasps and the King's medal with two clasps. He was D.A.D.M.S., Lowland Divn. (T.F.) in December, 1913, and later accompanied the Division to Gallipoli in the European war, and was in 1916–17 Deputy Assistant Director General at the War Office. Then he served on the Staff and as Deputy Director of Medical Services, Russian Expeditionary Force, being mentioned in despatches. He was created C.M.G. in 1916, C.B. (Mil.) 1918, and C.B.E. (Mil.) 1919. In 1924 he was appointed superintendent of the Edinburgh Royal Infirmary, and in February of this year had reached the retiring age of 65, but was asked to remain for another year. A note of appreciation of his work there appears in the letter from our Scottish correspondent this week.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, April 15th.

Odontology. 8 P.M. Mr. Harold Round and Dr. H. J. R. Kirkpatrick: Sequelæ following Injection Anæsthesia in the Mouth. Prof. W. H. Gilmour: Principles concerned in Tooth-cavity Preparation.

TUESDAY.

General Meeting of Fellows. 5.30 P.M. Ballot for election to the Fellowship.

CHELSEA CLINICAL SOCIETY.

TUESDAY, April 16th.—8.30 P.M. (Hotel Rembrandt Thurloe-place, S.W.), Mr. A. S. Blundell Bankart and Mr. Frank Romer: Manipulative Methods.

NORTH-WEST LONDON MEDICAL SOCIETY.

TUESDAY, April 16th.—9 P.M. (Regal Rooms, Regal Cinema. Finchley-road, N.W.), Dr. J. B. Mennell: Manipulation in General Practice.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE *MEDICAL ASSOCIATION*, 1, *Wimpole-street*, W.

SATURDAY, April 13th.—3 P.M. (Princess Beatrice Hospital, Richmond-road, S.W.), Mr. A. J. Wilson Chamings: Demonstration on diseases of the ear, nose, and throat. (Open only to members and associates of the Fellowship.)

PUBLIC DISPENSARY AND HOSPITAL, Leeds.

WEDNESDAY, April 17th.—4 P.M., Mr. L. N. Pyrah: Tuberculosis of the Genito-urinary Tract.

GENERAL INFIRMARY, Leeds.

TUESDAY, April 16th.—3.30 P.M., Mr. Pyrah: Demonstration of Surgical Cases.

UNIVERSITY OF BIRMINGHAM.

TUESDAY, April 16th.—3.30 P.M. (General Hospital), Dr. A. P. Thomson: Blood Pressure.

ROYAL INFIRMARY, Manchester.

TUESDAY, April 16th.—4.15 P.M., Mr H. T. Simmons: Anal Conditions.

ROYAL INFIRMARY, Dundee.

THURSDAY, April 18th.—3.15 P.M., Prof. Patrick: Cardiac Failure: Clinical Aspects. Prof. Cappell: Cardiac Failure: Pathological Aspects.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION,

WEDNESDAY, April 17th.—4.15 P.M. (Western Infirmary), *Dr. J. G. Macgregor-Robertson.*

Appointments

ATTKINS, L. C., L.D.S. R.C.S. Eng., has been appointed Dental Surgeon to the St. John Clinic, London.

BARWELL, HAROLD, M.B. Lond., F.R.C.S. Eng., Laryngologist to the St. John Clinic, London,

DOUGHERTY, F. N. B., M.B. Cape Town, Resident Medical Officer to the Royal Victoria Infirmary, Newcastle-upon-Tyne.

LESLIE, W., M.B. Lond., F.R.C.S. Eng., Senior Assistant Medical Officer (Grade I.) to St. Luke's Hospital, Chelsea, L.C.C.

MILES, EDWARD, M.B. Liverp., D.P.H., Medical Superintendent and Master of the Romford Institution.

WARD, E. M., M.B. Lond., Municipal Pathologist at Leicester.

London County Council School Medical Service.—The following appointments are announced :—

MCKEOWN, K. McC., M.D. Lond., D.P.H., Assistant Medical Officer ;

SCOTT, W. A., M.D. Belf., D.P.H., Assistant Medical Officer ;

WOODHEAD, B. E., M.B. Birm., M.R.C.P. Lond., D.P.H., Assistant Medical Officer ; and

POOLE, F. D. S., M.B. Lond., Medical Officer and Dental Anæsthetist at King's Canadian Residential Open-air School, Hampton-hill.

Vacancies

For further information refer to the advertisement columns

Aberdeen Royal Hospital for Sick Children.—Hon. Asst. Surgeon to Ear, Nose, and Throat Dept.

Aberdeen Royal Infirmary,—Hon. Asst. Phys. Also Hon. Jun. Asst. Surg. to Ear, Nose, and Throat Dept.

Banbury, Horton General Hospital.—Res. M.O. At rate of £150.

Bangor, Cærnarvonshire and Anglesey Infirmary.—H.P. £125.

Bath Royal United Hospital.—Out-Patient and Cas. O. At rate of £150.

Erdington House.—Jun. Asst. M.O.'s. Each at £200.

ospital, Wandsworth Common, S.W.—H.P. At rate

yal Infirmary.—Two H.S.'s. Each at rate of £135.

yal Alexandra Hospital for Sick Children.—H.S.

British Legion Village, Preston Hall, near Maidstone.—Asst. to Med. Director. £500.

Burnley Municipal General Hospital.—Jun. Res. M.O. £150.

Canterbury, Kent and Canterbury Hospital.—Two Hon. Anæsthetists.

Cardiff Royal Infirmary.—Res. M.O. and Res. Surg. O. Each at rate of £200.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall.—H.P. At rate of £150.

Chester Royal Infirmary.—H.S. £150. Also Hon. Asst. Phys.

Chesterfield and North Derbyshire Royal Hospital.—H.S. At rate of £150.

City of London Hospital for Diseases of the Heart and Lungs, Victoria-park, E.—Registrar. Also Asst. Radiologist.

Denbigh, North Wales Sanatorium.—H.P. At rate of £100.

Dewsbury and District General Infirmary.—H.S. £150.

Doncaster Royal Infirmary.—Cas. H.S. £175.

Dorchester, Dorset Mental Hospital, Herrison.—Sen. Asst. M.O. £450.

Eastbourne, Royal Eye Hospital, Pevensey road.—H.S. £100.

Eastbourne, Princess Alice Memorial Hospital.—Res. H.S. £150.

Evelina Hospital for Sick Children, Southwark, S.E.—H.S. At rate of £120.

Glamorgan County Council.—Asst. M.O. £400.

Guy's Hospital, S.E.—Astley Cooper Studentship.

Halifax Royal Infirmary.—Res. Surg. O. At rate of £250.

Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—H.S. At rate of £100.

Harrogate, Royal Bath Hospital.—Res. M.O. At rate of £156.

Herefordshire General Hospital.—H.S. and Cas. O. At rate of £100.

Hong Kong University.—Professor of Obstetrics and Gynæcology. £1000–50–£1100.

Huddersfield Royal Infirmary.—Res. Surg. O. £225–£250.

Ilford Borough.—Asst. M.O.H. £600.

Inverness, Royal Northern Infirmary.—H.S. At rate of £100.

Lancaster Royal Infirmary.—Jun. H.S. At rate of £130.

Leeds Education Committee.—Asst. School M.O. £500.

Leeds, St. James's Hospital.—Visiting Anæsthetist. £100.

Leicester City.—M.O.H. £1400.

Liphook, Hants, King George's Sanatorium.—Asst. M.O. At rate of £200.

London County Council.—Asst. M.O.'s. Each £470.

London Hospital Medical College, E.—Liddell Triennial Prize. £120.

London Homœopathic Hospital, Great Ormond-street, W.C.—Two Res. M.O.'s. Each £100.

London Jewish Hospital, Stepney Green, E.—Res. M.O. and H.P. At rate of £150. Also H.S. and Cas. O. Each at rate of £100.

Manchester, Ancoats Hospital.—Res. M.O. At rate of £150. Also Med. Reg. £50.

Manchester Ear Hospital, Grosvenor-square.—H.S. At rate of £150.

Manchester, Monsall Hospital for Infectious Diseases.—Asst. M.O. £350.

Manchester, Royal Children's Hospital, Pendlebury.—Res. Surg. O. At rate of £125.

National Hospital, Queen-square, W.C.—Hon. Surg. Asst., Asst. Surg., Asst. Phys., and Anæsthetist.

Newark General Hospital.—Res. H.S. £175.

Newcastle General Hospital.—H.S. At rate of £150.

Norwood and District Cottage Hospital.—Hon. Anæsthetist.

Nottingham and Midland Eye Infirmary. Res. H.S. £200.

Preston, Sharoe Green Hospital.—Sen. Asst. Res. M.O. At rate of £150.

Princess Beatrice Hospital, Earl's Court, S.W.—Hon. Clinical Assts. Also two Hon. Anæsthetists.

Queen's Hospital for Children, Hackney-road, E.—Asst. Phys.

Reading, Royal Berkshire Hospital,—H.P. and H.S., H.S. to Special Depts., Cas. O. Each at rate of £125.

Rochester, St. Bartholomew's Hospital.—H.P. At rate of £175.,

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.P. At rate of £100.

St. Alban's, Hill End Hospital, &c.—H.P. At rate of £165.

St. Bartholomew's Hospital, E.C.—Chief Asst. to X Ray Diagnostic Dept.

St. Leonard's Hospital, Hoxton-street, E.—Res. Med. Supt. £1000.

St. Marylebone, Borough of.—Two Asst. M.O.H.'s. £800.

St. Mary's Hospital, W.—Jun. Clin. Asst. for X Ray Dept. £50.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. and Asst. Res. M.O.s. At rate of £175 and £120 respectively.

St. Neots, Three Counties Hospital.—Med. Supt. £1000.

Sheffield Royal Infirmary.—Asst. Aural and Ophth. H.S. At rate of £80. Also Jun. Asst. Pathologist. £300.

Singapore, King Edward VII. College of Medicine.—$850 per mensem.

Southend-on-Sea General Hospital.—H.P. and Cas. O. Each at rate of £100.

Stockport Infirmary.—H.P. £150.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. for Aural and Ophth. Depts. Also Cas. H.S. Each at rate of £150.

Stoke-on-Trent, Stanfield Sanatorium.—Asst. Tuber. and Asst. M.O. £350.

Sunderland Royal Infirmary.—H.S. £120.

Swanley Hospital Convalescent Home, Parkwood.—Res. M.O. At rate of £200.

Truro, Royal Cornwall Infirmary,—H.S. £170.

University College Hospital, Gower-street, W.C.—Bilton Pollard Fellowship. £650.

West Bromwich, Hallam Hospital.—Res. H.P. At rate of £200.

West London Hospital, Hammersmith-road, W.—Res. Anæthetist. Also H.S. to Throat, Nose, and Ear Dept. Each at rate of £100. Hon. Asst. Anæsthetists.

Willesden Corporation.—Asst. M.O. £600.

Willesden General Hospital, Harlesden-road, N.W.—Cas. O. At rate of £100.

Woolwich and District War Memorial Hospital, Shooter's Hill, S.E.—Hon. Laryngologist. Also Surg. Reg. £100.

Worksop, Victoria Hospital.—H.S. At rate of £160.

Births, Marriages, and Deaths

BIRTHS

ATKINSON.—On April 2nd, at Welbeck-street, the wife of E. Miles Atkinson, F.R.C.S. Eng., of Bath, of a daughter.

BANKS.—On March 31st, at Gurney-drive, Hampstead Garden Suburb, N., to the wife of A. Leslie Banks, M.D. Lond.—a son.

HOUSTON.—On April 2nd, the wife of N. Roy Houston, M.D. Q.U. Ont., F.R.C.S. Edin., of Tonbridge, Kent, of a son.

MCFARLANE.—On April 3rd, at Cheam, the wife of Arthur Sproul McFarlane, M.B. Glasg., of a son.

STRÖM-OLSEN.—On April 4th, at a London nursing-home, the wife of Rolf Ström-Olsen, M.D., B.Sc., D.P.M., of a daughter.

THOMAS.—On April 4th, at Aldermaston, Berks, the wife of G. Wynne Thomas, M.B. Camb., of a daughter.

UNGLEY.—On April 3rd, at Whickham, Newcastle-upon-Tyne, the wife of C. C. Ungley, M.D., of a daughter.

WILLIAMSON.—On April 4th, the wife of James C. F. Lloyd Williamson, F.R.C.S. Eng., of Hove, of a son.

MARRIAGES

GIMBLETT—MCNICOL.—On April 4th, at St. Columba's, Pont-street, London, Charles Leonard Gimblett, M.D. Camb., F.R.C.S. Eng., Devonshire-place, W., to Audreen McNicol, daughter of Mr. and Mrs. Duncan McNicol, Holland Park, W.

DEATHS

BAYLOR.—On March 30th, at The Orchard, Ash, Canterbury, Henry Talbot Baylor, L.R.C.S.I., Major, R.A.M.C. retd., aged 76.

BODINGTON.—On April 4th, suddenly, at Halesowen, Percival James, M.B. Edin., late Surgeon-Captain, R.H.G.

BRADFORD.—On April 7th, at Manchester-square, W., Sir John Rose Bradford, Bart., K.C.M.G., F.R.S., aged 71.

COLLIE.—On April 4th, at Porchester-terrace, W., Sir John Collie, C.M.G., M.D. Aberd., aged 74.

KING.—On April 4th, at Sevington-road, Hendon, N.W., Colonel Walter Gawen King, C.I.E., I.M.S., retd., in his 84th year.

NICHOLS.—On April 4th, suddenly, at Dawlish, Lieut.-Colonel Frederick Peter Nichols, M.B. Camb., M.R.C.S. Eng., R.A.M.C. retd., eldest son of the late William Peter Nichols, F.R.C.S., of Norwich, aged 78.

PECK.—On April 4th, Herbert Peck, M.D. Edin., D.P.H., Barrister-at-Law, of Hasland, Chesterfield, in his 74th year.

SHARDLOW.—On March 31st, at Hove, Sussex, Joseph Shardlow, M.B. Lond., M.R.C.S. Eng., Captain R.A.M.C. (T.), aged 63 years.

YELD.—On April 3rd, at Edgewood, B.C., Reginald Arthur Yeld, M.D. Camb.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

PREVENTION OF THE COMMON COLD *

BY ERNEST WARD, M.D. Camb., F.R.C.S. Eng.
HON. SECRETARY, JOINT TUBERCULOSIS COUNCIL

FIRST, what is the "Common Cold"? It is an endemic virus disease accompanied by coryza, pharyngitis, tracheitis, and some bronchitis, and complicated after the first infection by the growth of various other parasitic organisms, such as pneumococcus, streptococcus, staphylococcus, *Micrococcus catarrhalis*, and Pfeiffer's bacillus. In addition to the endemic there are epidemic waves, of which three main ones can be traced each year; the first in October and November—the autumn cold; the second in January and February—the winter cold; and the third in April or May—the spring cold. Of these the most severe is the winter cold, often accompanied by pyrexia and a wealth of other symptoms which have induced observers to name it influenza. There is no proof that influenza is a distinct disease, and it is just as likely that the cold virus causes a polymorphic reaction in different individuals similar to the streptococcus, which has been incriminated as the causative organism of cellulitis, scarlet fever, acute rheumatism, chorea, erysipelas, malignant endocarditis, puerperal fever, and impetigo. In any epidemics a similar train of symptoms is likely to prevail among the victims, and these may be toxic, catarrhal, gastric, enteric, colitic, cardiac, pulmonary, nephritic, and cerebral. There are other causes of coryza, pharyngitis, and tracheitis in addition to the common cold, for these symptoms are common at the onset of known specific fevers, and probably also of attacks from other parasitic organisms not yet identified.

Next, what is the origin of the immunity to colds which both prevents their incidence and terminates their attacks? The immunity is both congenital and acquired. Acquired immunity varies according to the individual attacked and the nature of the attack, but is usually short-lived, 1 to 6 months, and immunity acquired to a coryzal attack may not withstand an attack in which the prevailing symptoms are gastric, enteric, or in any other way atypical. Far and away the most important immunity is congenital, and it is on account of this that some individuals never "catch cold," and others but rarely, say every few years. A similar congenital immunity is found to all disease, and very definitely to tuberculosis, or the population would long ago have died out or been gradually replaced by an immune population.

How can colds be prevented? No doubt such precautions as avoiding chill or worry, wet feet, exposure to infection, or becoming over-tired, as advocated each autumn in all popular newspapers, have a certain limited value, but these precautions cannot always be followed by those leading a life of normal activity; so we have to consider other more strictly medical measures. Of the mechanism of congenital immunity we know nothing, and so are entirely unable to confer it artificially; research in this direction, if successful, would be of inestimable value to the community.

In the search for an artificially acquired immunity we are handicapped first, by the short duration of the natural immunity—an exemption even if successfully produced, but enduring only 1 to 6 months, would be of doubtful utility; secondly, by our lack of knowledge of the causative organism and the failure to cultivate it on artificial media. So that any vaccine therapy becomes haphazard and non-specific, depending rather on arousing latent powers, such as may occur in cases of sarcoma treated with Coley's fluid, or arthritis with T.A.B. vaccine, and protection from concomitant infections, than the creation of protection against the chief morbid agent. Observing, as do most practitioners, a large number of attempts to protect against colds by various methods of vaccination leaves an impression of disappointment and disbelief. Single cases and special methods may be noted and vaunted, but the result, when the numbers are sufficiently large to merit serious consideration, is invariably disappointing.

A host of other prophylactic measures have been advocated—physical methods, such as cold baths in the morning, bathing chest and neck with cold salt water night and morning, dietetic methods, such as the ingestion of fats (bacon and cod-liver oil) and vitamins A, B, or D, and treatment by various drugs, such as cinnamon, quinine, belladonna, camphor, citrates, and strychnine, but none of these can really be relied upon, and the same applies to local applications by brush, gargling, or nasal douche. In years when colds are scarce the advocates of all these methods will be quoting successes, but nothing will be heard from them in the seasons when colds are frequent and severe.

My own conclusion is that nothing will protect a susceptible subject from the three principal colds of the year, but it may be possible to assist him to avoid intermediate infections if the patient at risk is reasonably careful to avoid exposure to sources of infection, or excessive chilling of the skin surface, and takes cod-liver oil emulsion or some other form of cod-liver oil during the autumn and winter months.

---

* A memorandum prepared at the request of the Joint Tuberculosis Council.

A HISTORY OF GERMAN MEDICINE

A CONCISE account of the development of medicine in Germany from the earliest times up to the present day is given by Prof. Haberling [1] in a little book excellently translated into English by Jules Freund. The story is well balanced, impartial, and evidently embodies a vast amount of research.

When the black death (bubonic plague) ravaged Germany in 1348 no medical help was available because the ancient writers on whom reliance was then placed mentioned no remedies, and to make matters worse foreign universities refused to admit German students for fear that they should bring the infection. Accordingly, the first German university was founded at Prague in 1248 and several more during the next century—e.g., Erfurt 1382, Heidelberg 1386, Cologne 1388, and Leipzig 1409. The course in medicine, it seems, was expensive and frequently took six years, so that students were comparatively few; and at each centre there were seldom more than two professors, one of whom taught the theory, the other the practice of medicine. Dissection of the cadaver did not become general until about a hundred years after it was introduced at Bologna in 1315. German students, however, had to make obligatory visits to the pharmacies. Owing to the uncrowded state of the profession, physicians in Germany in the fourteenth century enjoyed a high status and were exempt from taxes. In certain statutes at Nuremburg in 1350 and in Silesia it was forbidden on the one hand that physicians should prepare medicines themselves, and on the other that pharmacists should treat patients. Municipalities that could afford it often appointed physicians of their own and some of these "town physicians" became famous.

It is curious that the Germans, who have since proved such adepts at the experimental method in all its branches, should have taken so long to get going; for centuries their physicians, like those of other nations, were content to rely upon the imagination rather than set to work and find out what was actually happening in the human body in health and disease. The first of two important factors in the awakening was the invention of printing in Germany by Guthenberg. The first medical book was by an unknown author and was printed at Augsburg in 1472. In the same year at Ulm a treatise on plague by the town physician Steinhövel was printed: it ran into several editions and continued with modifications until the eighteenth century. In 1484 the first book on botany, "The Garden of Health," by Peter Shoeffer, was printed at Mainz, the birthplace of printing. According to Prof. Haberling, some of these early German herbals by physicians who are called the "fathers of botany" are extremely attractive, their illustrations being beautifully executed. The second event that led to the great awakening was the fall of Constantinople in 1483, which caused the emigration of countless Greek scholars to other parts of Europe; they brought with them precious manuscripts of the ancient physicians and taught Greek to others. In editing these ancient transcripts German physicians were prominent, and one of them, Johannes Hagenbutt (1500–58), after 15 years of labour, brought out a new edition of all the works of Hippocrates that had survived.

---

[1] A History of German Medicine. By W. Haberling, Professor of the History of Medicine, Düsseldorf. Translated by Jules Freund. Clio medica series. New York: Paul Hoeber. 1934. Pp. 160. $1.50.

The first great German physician to probe deeply into the secrets of nature was Theophrast von Hobernheim, who belonged to an old aristocratic Swabian family, was born in 1493, and is known to-day as Paracelsus. His father, a learned physician, taught him how to extract drugs from the leaves, petals, roots, and stems of various plants, and also taught him how to look for metals in urine and to produce new chemical compounds by melting them and combining them with other metals. Paracelsus devoted his life to searching for new chemical compounds that would help the human body back to health after severe illness. He travelled widely and studied the characteristics of all kinds of metals and used this knowledge in the most varied diseases. His success was great, and, as Prof. Haberling points out, he created new drugs and was thus the father of the chemotherapy of to-day. In addition to his researches Paracelsus performed a great service by fighting with all his might against the healing methods of his contemporaries, who relied entirely on the books of the ancients; and he also saw the futility of the doctrine then prevalent of the "Four Humours." He set himself to build a new science founded on experience and experiment. His works were chiefly issued in German, and for that reason had a wider circulation than would have been the case had they been written in Latin, as was then usual. He met with much jealousy and persecution, and the printing of some of his best books was prohibited by the medical faculties of Leipzig and Vienna; but they were published by his followers after his death. He died at Salzburg in 1541 in his forty-eighth year. A fine and complete edition of his works in 14 volumes has recently been brought out by Paul Sudhoff, the well-known medical historian.

The early history of German surgery is also described by Prof. Haberling. In 1497 a beautiful book "Die Chirurgia," by Hieronymus Brunschwig of Strassburg, appeared; it was the first work to give an adequate description of gunshot wounds. In 1583 a good presentation of contemporary ophthalmology was published by Bartisch, who was the first to extirpate the eyeball, and also operated for cataract. He opposed eyeglasses, which had already become fashionable though they were extremely expensive, costing from 60 to 150 marks. It is interesting to note that in 1567 Johann Weier, who was physician to the Duke of Cleves, wrote a book in which he pointed out that so-called witches were not possessed by any devil or demon but simply hysterical or melancholic old women who ought to be treated for their malady and not killed as witches. The book had several editions, but failed to carry conviction.

In the seventeenth century Harvey's great book on the circulation was published at Frankfort in 1628 and was received with enthusiasm in Germany. By 1632 Rolfinck, professor of anatomy and chemistry in Jena, had publicly accepted Harvey's views, and in 1640 Conring, a professor at Helmstadt, published experiments on living animals confirming Harvey's thesis and refuting his opponents in Paris and elsewhere. Valuable support of Harvey was also given by Slegel of Jena, whose work defending him against Riolan and giving a clear description of the fœtal circulation was published in 1650.

Among German physicians of the seventeenth century are several famous names, including Schneider of the Schneiderian membrane, Peyer of the "patches" in the small intestine, Brunner of gland fame, Wirsung, who in 1642 called attention to the pancreatic duct, and Vesling, who in 1647 was the first accurately to describe the suprarenals. In 1638 Hauptman and Lange put forward a curious theory in which they ascribed the origin of disease to parasites, worms, mites, and other small living beings that developed in decaying vegetable matter. Their "Pathologica animata" contains a description of wondrous little beings discovered by them with the microscope in various tissues and fluids of the human body.

In the eighteenth century Stahl and von Haller were pre-eminent. The former produced a curious system of medicine that Prof. Haberling describes, but in his opinion Albrecht von Haller of Gottingen (1708–71) was the greatest German figure in medicine after Paracelsus both as physician and investigator until the nineteenth century. Finally, the great German investigators and physicians during the past hundred years are all described in turn in this excellent little book, which also gives an account of the scientific study of the history of medicine that is now being carried on in Germany.

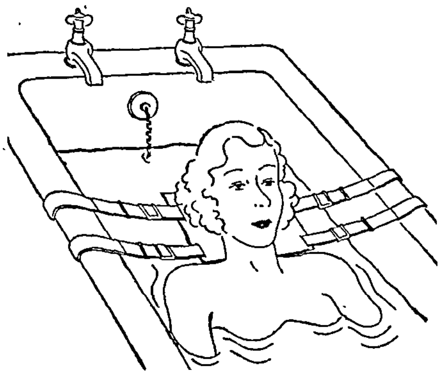
TREATMENT OF ACUTE OSTEOMYELITIS

AT a recent meeting of the New England Surgical Society (New Eng. Jour. Med., Feb. 14th, 1935, p. 283), Dr. Richard H. Miller made a plea for early operation and also advocated frequent irrigation of the operation wound with renewed packings, under strictly aseptic conditions, during the acute stage. Some of the subsequent speakers did not agree with him; thus Dr. Robert B. Osgood recommended that where osteomyelitis is established and the child is very ill, an attempt should be made by means of sedatives and fluids to restore general condition and resistance before operation is attempted. He holds that in some of these cases the surgeon will do well to wait for 12–24 hours. Dr. William E. Ladd went further in advocating a delay of two or three days in certain cases, and, in his reply, Dr. Miller agreed that there were cases in which a period of restoration might be necessary. A sharper division of opinion arose concerning the value or harm of frequent dressings. Osgood expressed himself as strongly in favour of the Winnett Orr method, in which the limb is encased in plaster, and dressings are reduced to a minimum; and Dr. Lyman Allen maintained that irrigation is unnecessary and that frequent dressings in young children are actually harmful. The method to be used in localising the pus, in cases where subperiosteal suppuration has not occurred, was also discussed. Miller favoured repeated drilling of the bone with a ¼-in. burr until pus is reached, whereas Osgood considered that this carries the danger of infecting healthy bone; it is much better, he thinks, to remove a generous cap of cortex over the metaphysis and, using a strong direct light, to search gently with a probe for the focus of infection, and to determine its extent before instituting drainage. Allen believes that opening of the marrow cavity may be unnecessary, drainage being limited to a localised abscess in the cortex. Various warnings were uttered against excessively radical operation on children under two years old or in neglected cases first seen 2–4 weeks after the onset; and Ladd said that with small infants his practice at the first operation was to open the periosteum only. In this connexion interest attaches to Osgood's opinion that in infants the infecting organism is twice as frequently a streptococcus (usually hæmolytic) as a staphylococcus, and that in streptococcal lesions in infants less complete drainage is required.

The importance of making the diagnosis on fever, pain, local tenderness, and the white cell count, without waiting for localised swelling or changes demonstrable by radiology, and the significance of strictly localised pain in determining the part of the bone affected, were clearly brought out in the discussion.

HEAD-REST FOR THE BATH

THE head-rest here illustrated meets a need which must have been felt by many bath-users—if inarticulately. Its chief appeal will be to those who like to revel in hot water, and on persons of irresolute character its influence may thus be anti-social rather than otherwise. As an aid to nursing, however, it should more than redress the balance, for there is always difficulty in supporting the head and shoulders of a patient while attending to the other operations of the bath, and the head-rest may mean that one nurse can do the work of two. Furthermore, it will allow a person to lie in comfort in a medicated bath, with the shoulders submerged—a situation not easily arranged otherwise. The model now available at the principal druggists and large stores is made of rubber and stainless steel, and should give full satisfaction; the straps are adjustable to fit any width of bath. The name given to it is the "Heavenly" bath head-rest, and it is produced by Louisa Slater, of London.



SHAKESPEARE AS PSYCHIATRIST[1]

THE psychological wisdom displayed by Shakespeare has been the subject of comment, learned and otherwise, in many countries and for many years. To the number of writers on the subject may now be added Dr. André Adnès, who occupies an important residential post in a French mental hospital. He was induced to write the book because in his opinion of all the great dramatists Shakespeare more than any other had depicted accurately the aspects of mental disorder. This fact has struck many writers medical and lay before, as is evident from the copious bibliography supplied by Dr. Adnès, which moreover is far from complete. The remarkable familiarity with the outward aspects of insanity which may be seen in so much of Shakespeare's writing undoubtedly had its origin in the fact that in the absence of institutional provision the person of disordered mind, when not actually secluded as though a criminal, lived with the general population. His divagations from the normal were therefore so well known to general observation that Shakespeare could rely upon his descriptions being readily appreciated. Dr. Adnès must be congratulated upon his accurate knowledge of his subject. "Le xviie. siècle anglais," he writes, "qui devait donner au monde médical Harvey, le physiologiste, Sydenham, clincien et thérapeute, et Willis, neuro-pathologiste, vit à son début, William Shakespeare, auteur dramatique publier des observations psychiâtriques remarquables, dont la vérité clinique n'a pas vieilli; au courant de toutes les théories scientifiques de son temps, il nous les expose au complet, sans systématisation, en les illustrant d'exemples; il nous présente encore toutes les croyances populaires et superstitieuses d'alors. Shakespeare nous apporte sur la folie et son traitement à son époque la documentation la plus complète que nous possédions." He supports this magnificent claim for Shakespeare by analyses of scores of characters from "Hamlet," and "Lear," and other protagonists of the great dramas down to the holders of quite minor rôles, and supplies in doing so a learned and well-written chapter in medical criticism.

A MAP OF LONDON FOR EASY REFERENCE

WE have received from the Lightning Cities and Road Map Co., Ltd. (20, Holborn, London, E.C.1), a plan of London, city and suburban, with a system of reference by which any place name can be found in a few seconds. The map, although it covers the whole of London, from Golders Green and Leyton in the north to Kingston and Chislehurst in the south, on a scale of three inches to the mile, is contained in a folder 9½ by 6½ in., and need never be stretched out. The index must contain more than 16,000 names, to each of which two numbers are attached corresponding with figures at the side and top of the folder. To identify a street it is only necessary to find these figures, and to note where the verticals from these points meet on the plan. The map has been printed in five colours by the Ordnance Survey and indicates railways with red stations above and below ground, yellow omnibus and tram routes, green spaces, and blue sheets of water. It has evidently been brought carefully up to date. The map is called the Lightning Plan and is well worth 4*s.* 6*d.* It may well serve the practitioner's purpose better than an expensive atlas. It is proposed to publish on a similar principle a motor map of England and Wales on a scale of three miles to the inch in fourteen sections.

UNIVERSITIES YEAR BOOK 1935.—Sir Frank Heath's name no longer appears on the title-page of this admirable compilation, as he retired from the office of editor after preparing the five issues, 1930 to 1934. The Year Book contains no new features, but there is evidence of increasing care and promptitude in the returns made by registrars and others, and it can be counted upon more than ever for giving recent and precise information about any of the universities of the Empire, which now number seventy. The Year Book is published by Messrs. G. Bell and Sons at 15*s.*, and it is accompanied by a notice that the fifth quinquennial congress of Universities of the Empire, organised by the Universities Bureau, will be held at Cambridge from July 13th to 17th, 1936.

REGISTER OF VETERINARY SURGEONS.—We have received from the Secretary of the Royal College of Veterinary Surgeons (10, Red Lion-square, London, W.C.1) a copy of the Register revised up to Jan. 1st, 1935. The total number of registered veterinary surgeons at that date was 3440, being 31 more than a twelvemonth earlier. During the year 1934 81 deaths were recorded and 6 names were removed for other reasons, which were more than counterbalanced by 115 new graduates and 3 names restored. The second list in the Register, being existing practitioners registered under the Act of 1881, is diminished to 23. The volume which is published under Parliamentary authority contains the by-laws of the College and much information about qualifying for the veterinary profession. It is to be obtained from the College for 5*s.*, which is also the price of the separate volume of Acts and Charters.

ADDRESSES AND ORIGINAL ARTICLES

SO-CALLED ACIDOSIS ATTACKS

A PLEA FOR MORE ACCURATE DIAGNOSIS*

BY DONALD PATERSON, M.D. Edin., F.R.C.P. Lond.
PHYSICIAN, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON; PHYSICIAN FOR DISEASES OF CHILDREN, WESTMINSTER HOSPITAL

ONE of the commonest diagnoses in children's medicine to-day is that of "acidosis." Hardly a day passes that I do not see a case named as such. The symptoms with which the children present themselves are usually fever, vomiting, or diarrhœa, with pale motions; and of late I have noticed a slight tendency on the part of some doctors and parents to doubt whether the explanation covers the facts.

By acidosis is meant the formation of ketone bodies in the blood and urine; that is, the presence of acetone and diacetic acid on the breath, in the blood, and in the urine. Biochemical acidosis, brought about by the shift of the pH of the blood to the acid side, induced by mineral acids, is not what is usually meant by the term as it is used in the clinical sense. It is the *clinical* meaning of acidosis or ketosis which I propose discussing.

The metabolism of the fats is profoundly influenced by the balance between fats and carbohydrates, and if the carbohydrate in the form of starches and sugars be insufficient, the fat will be only partially broken down, and acetone and diacetic acid will be formed. This may be brought about because the amount of carbohydrate absorbed is insufficient, or because too much fat is being given. The usual sequence of events, however, is that the carbohydrate present in the food, and stored in the muscles and liver, is suddenly called upon and used up during an infection. The body, deprived of carbohydrate, looks to its store of fat for energy, and ketone bodies are formed as a result. It may be said then that it is normal for each and every individual with an acute infection to form ketone bodies, and it has been common knowledge for many years that acetone and diacetic acid are the usual constituents of the urine of acutely febrile children. Put shortly, there is nothing very unusual or strange about the presence of ketone bodies in the urine of infected children.

Now what symptoms arise as a result of acetone and diacetic acid being present in the blood and urine of an infant or child? It is difficult to assess the part they play, but a series of experiments done under my eye in the Westminster Hospital some years ago by R. W. B. Ellis[1] impressed me by the lack of clinical signs and symptoms associated with ketogenic diet. The diet used was—

8 A.M.: Olive, half, ½ oz.; ol. morrhuæ, drachms 3; fried fish or sardines, 2 oz.; top milk, 6 oz.; bran biscuits, ad lib.; one slice of white bread; butter, 1 oz.

12.30 P.M.: Minced beef, 3 oz.; cabbage, 2 oz.; butter, 1 oz.; olive oil, ½ oz.; ol. morrhuæ, drachms 3; top rice-pudding, 1 oz.

4.30 P.M.: Fat ham or bacon, 2 oz.; butter, 1 oz.; top milk, 6 oz.; olive oil, ½ oz.; ol. morrhuæ, drachms 3; bran biscuits, ad lib.

Normal children were put on this diet until the urine was heavy with acetone, but apart from a poor appetite and a stationary weight chart they had no symptoms. There was no vomiting, languor, sighing respiration, pallor, or other symptoms so commonly attributed to the presence of acetone; in fact, they were clean-tongued and cheerful, though they lacked appetite or wish for food. The same result may be seen in the epileptic child having a ketogenic diet, and left on it for many months. No great difficulty is found in maintaining the diet, and few symptoms arise from it.

I would stress the fact, then, that in the vast majority of children acidosis or ketosis by itself leads to little or no change in the clinical picture. We must conclude that the symptoms attributed to "acidosis" are produced by the factor which produces the acetone—and this is usually an infection.

Cause of Cyclical Vomiting

To throw some light on this problem, let me turn to the old-fashioned condition termed "cyclical vomiting," which in its extreme form is a comparative rarity to-day. Usually it is described in this way—a thin, nervous child, of neurotic unstable stock, gets recurrent bouts of vomiting at short intervals, possibly every three or four weeks. These attacks are ushered in by yawning, pallor, lassitude, and irritability for a few hours, and during this period the sweet smell of acetone may be detected on the breath. The temperature is found to be raised, but not particularly high. A few hours later vomiting commences. This is so severe that not even a teaspoonful of water is kept down. The child rapidly becomes sunken and drowsy, the abdomen is scaphoid, and finally the vomit may be coffee-ground, or may even contain bright blood. After two or three days the vomiting suddenly ceases, and in the most dramatic fashion the child recovers. An examination of the urine throughout shows the presence of acetone and diacetic acid. There is often a complaint of abdominal pain or discomfort, but usually this *follows* the vomiting rather than precedes it.

Children with typical cyclical vomiting have been admitted to hospital, in various parts of the world, for investigation. Findlay[2] found that a cyclical vomiter, just recovering from a typical attack, continued to improve, and recovered well, while actually on a ketogenic diet, and he was unable to cause attacks of vomiting in such children by giving them a ketogenic diet while they were in hospital, although their urine contained much acetone. Ellis[1] put two children who were typical cyclical vomiters and also two children who had had fever and convulsions (with acetone in their urine and cerebro-spinal fluid) on a high fat-low carbohydrate diet; and although all developed a marked ketosis, and the cerebro-spinal fluid of the second two contained much acetone, no vomiting or other symptoms developed.

It appears then that there must be some missing factor, other than the production of acetone, to account for the clinical picture in cases of cyclical vomiting.

Graham and Morris,[3] who likewise failed to produce symptoms in children on a ketogenic diet, have concluded that a low blood-sugar (hypoglycæmia) is not, as some hold, responsible for the ketosis or vomiting; for the children they investigated showed a normal or, in fact, a raised blood-sugar. Their investigations have led them to believe that there is an impaired hepatic function; they have found urobilin in the urine during an attack, and the lævulose-tolerance test bears this out. Holt and McIntosh,[4] on the other hand, think that cyclical vomiting is associated with neurotic stock, and that a low blood-sugar plays a definite part in it. John Thomson[5] maintained that the liver showed an accumulation of fats, especially in neurotic children, and that there was some connexion between these attacks and migraine, sick headache, asthma, and eczema.

Bray,[6] discussing migraine, suggests that most cases of cyclical vomiting in childhood are, in fact, abdominal migraine, but he points out that the attack of migraine rarely lasts more than 24 hours. It recurs at very frequent intervals, from two to three times a week to once a month, and acetone is not commonly present. Headache is usually prominent. Payne[7] regards cyclical vomiting as a metabolic disturbance centred in the liver. J. C. Spence [8] holds that it is due to a recurrent toxæmia from some such cause as tonsillitis or hepatitis. The vomiting and drowsiness are identical with the vomiting and drowsiness seen at the onset of many acute febrile illnesses, and the ketosis is a mere epiphenomenon.

---

* Given before the South-West London Medical Society on Feb. 13th.

Reginald Miller [9] says that cyclical vomiting attacks are due to an acute poisoning of the liver, which often shows itself by pale stools, and he suggests that a diminished glycogen reserve in the liver renders that organ vulnerable to poisons, and certainly an intestinal toxæmia. He thinks that the withholding of a normal supply of fat in the diet is unnecessary, and may be harmful.

An excellent description of cyclical vomiting, and of the child most prone to such attacks, has been given by H. C. Cameron[12] in his book "The Nervous Child"; but it seems to me that he puts too much emphasis on the constitutional and psychological side, and on the effects of the ketosis. He points out the value of carbohydrate, especially glucose, in such cases, but he evidently does not consider infections as a common cause of the symptoms described.

Most authorities agree that cyclical vomiting is a metabolic disturbance; they cannot decide whether this disturbance is due to infective, dietetic, psychological, or allergic factors. My own feeling is that far too little stress has been laid on infection as the cause of the attacks. There can be no doubt that the vast majority are accompanied by fever, especially at the start, and that the old term "chill on the liver" describes the condition extremely well. Unfortunately even the absence of fever does not exclude infection.

A boy, aged 5 years 9 months, was seen by me on Jan. 19th, with a normal temperature and normal ears, at 10 A.M. At 4 P.M. he complained of slight earache, and at 10 P.M. his drums were red and inclined to bulge. For the next day or two the situation remained unchanged; then they gradually subsided. At no time was the child's temperature more than 98° F., and the urine contained acetone throughout.

Very often the practitioner is asked to see the child when the vomiting has already begun. A full 24 hours or more may have elapsed since the prodromal symptoms appeared, and the signs of infection are then less obvious. Children show widely differing reactions to infections. On the one hand you have slight nasal catarrh, accompanied by diarrhœa, or acute tonsillitis accompanied by a high fever and vomiting. A thin, nervous, wiry child may show little or no outward sign of his infection; nevertheless, it may be present.

Post-mortem examinations of cases of cyclical vomiting show conspicuous fatty changes in the liver. Urobilin in the urine and indeed definite jaundice have sometimes developed in typical cases, and I think one should assume that the underlying pathology always includes some degree of cloudy swelling of the liver cells, brought about by an infection—most often a passing cold or sore-throat.

Dangers of Diagnosing Acidosis

When a doctor is presented with a feverish and vomiting child who has acetone in the urine, an acceptance of the diagnosis of acidosis carries with it grave risk of missing gross organic disease. I have often seen cases wrongly given this diagnosis, and later proved to be abdominal tuberculosis, appendicitis, pyelitis, typhoid, or lobar pneumonia. There are classical cases, some of the best being those reported by Poynton,[10] in which partial volvulus of the small intestine gave rise to symptoms of vomiting with abdominal pain, and the production of much acetone and diacetic acid. There is a great tendency for the volvulus to right itself and then recur a few weeks or months later. In such cases the abdomen is distended, and the pain marked, whereas in the true cyclical vomiter there is a scaphoid abdomen, and the pain follows the vomiting instead of preceding it.

A practitioner should pause, therefore, before making the diagnosis of acidosis, all the more when reminded that it is one very little used in a children's hospital. For instance, out of many thousands of admissions, over a period of ten years, it only appeared six times at Great Ormond-street.

The usual case which a practitioner is called to see and treat is not one of the extreme degree which I have depicted, but merely of a feverish child who has had probably less than half a dozen vomits, and who has an offensive breath, dirty tongue, pale stools, and a disinclination for food. After a day on light fat-free diet, the patient is well or nearly well, the whole thing being over in two or three days. A careful examination of the nasopharynx and ears will usually reveal the presence of an infection.

Treatment of Cyclical Vomiting

When two or three of these attacks have occurred, and the label of "acidosis" has been attached to them, it is said that such children tolerate fat badly, and they are put on a diet extremely low in fat and high in carbohydrate. This usually contains little or no milk, and what is given has been skimmed. Extra glucose is given during the day, in varying quantities, and vitamin D may be added. The low-fat diet may be continued for many months, or even years, but this I believe to be a complete mistake. During the actual attack fats in the form of milk, butter, cream, egg-yolk, dripping, and oils, including cod- and halibut-liver oil, should be rigorously excluded; but once the attack is over the child should be put back once more on to a normal diet. It is reasonable to expect, especially in slight cases, that an interval of a few months may pass, even if nothing is done in the way of prevention, before another attack need be expected, and I believe it to be a mistake to deprive a child of a normal diet because of the chance of another attack.

If you were faced with the treatment of a case of epilepsy in which a child had a fit once or twice a year, would you give bromide or some other drug each and every day to prevent that remote possibility? I doubt it. If, by keeping the child who gets acidosis on a rigorous low fat-high carbohydrate diet continuously, one were sure of preventing further attacks, there might be some slight grounds for doing it, but this is not so. In my opinion, the next sharp infection —such as influenza, scarlet fever, or acute sore-throat —would produce another of the attacks; and a straightforward infection, which ought to be easily understood, becomes shrouded in a mist of words such as "acetone" and "acidosis."

In the treatment of an acute attack most careful examination is necessary to exclude organic disease. A good view of the throat must be obtained at the risk of causing further vomiting. The ears should be seen and the abdomen carefully palpated. The mother should be questioned as to the presence of abdominal pain, and it should be especially noted whether the pain preceded or followed the vomiting. If it preceded it, abdominal disease of some description should be suspected and searched for. The lungs should not be forgotten, for a deep-seated lobar pneumonia may begin with fever and vomiting. Once the practitioner has made up his mind that this is a mild infective hepatitis, the administration of glucose, either in its fluid form or as powder by the mouth, or with saline subcutaneously, rectally, or intravenously, should be proceeded with immediately, especially if the vomiting is severe. In severe cases I have seen patients become comatose, and even die, for lack of treatment.

It is impossible to know when a simple case may become a more severe one, so each attack should be taken seriously. Where there is much vomiting constipation is usually present also, and advantage should be taken of this fact to give rectal saline and glucose. The help of the district nurse should be obtained. Even if the saline and glucose is returned, it will cause the bowels to be opened, which is an advantage. Where there is diarrhœa, vomiting is usually much less severe, and the giving of glucose by the mouth will rapidly remove the acetone and provide the body with easily assimilated food which requires little or no work on the part of the liver.

Where an obvious nasopharyngeal infection exists, treatment of the throat with powdered aspirin, or the bulging red ear-drums by incision, will bring about cessation of the vomiting. It is seldom a good thing to give bicarbonate of soda to these children after the vomiting has commenced.

Prevention

Most good can be done in the prevention of the attacks. If the primary infection be in the tonsils and adenoids these should be removed, and in my experience this has prevented the vast majority from having further attacks. Occasionally, especially in girls, examination of the urine will reveal pus, showing that each attack was really a recurrence of acute pyelitis. A well-balanced diet will maintain a better standard of health and nutrition, and thus lay the child open to fewer infections, so that fewer attacks are precipitated. So often one sees the victims of an anti-acidosis diet with every tooth stopped, a thin emaciated body, and a dry skin. The treatment has made the child much more ill than the actual attacks themselves.

A diagnosis of acidosis often suggests that the fault lies in the mother or nurse, and that their dieting and management have been at fault. Surely this is an unfair assumption. The prevention of ordinary infections by the strict isolation of children with common colds is becoming commoner. The mother of a child especially prone to chills on the liver may do much to forestall an attack by watching the stools daily; when they become pale she can reduce the fat temporarily and administer some mild saline aperient. Whenever possible she should isolate the child from other children in the nursery who have colds, and at the first of the prodromal signs of yawning, lassitude, and pallor, which to me indicate the onset of an infection rather than only the formation of acetone, she should promptly administer glucose and summon the doctor. He may see fit, in appropriate cases, to give a little aspirin and a purge, and a great many of the attacks can in this way be aborted or checked before they really start.

I would sum up in this way: that the diagnosis of acidosis is a bad one, and should never be used. We ought rather to think of the process underlying this clinical picture. This will rarely be found to be primarily dietetic, but rather infective in origin. A search for the source of the infection, usually nasopharyngeal, should be made, and this should be treated. Prevention depends on educating the mother to be on the alert for the first signs of liver infection which gives rise to this symptomatic vomiting.

THE RADIOLOGY OF PNEUMONIA

(WITH ILLUSTRATIVE PLATES)

THE radiological changes caused by acute inflammatory diseases of the lungs have not been studied so extensively as those due to chronic diseases, partly because of difficulties in technique and partly because the patient is often too ill to allow of more than the briefest examination.

This paper is based on the radiological examination of 119 cases of pneumococcal pneumonia, and the results have been correlated with the clinical and bacteriological findings; during the investigation approximately 1500 radiograms were taken. The patients were all collected in one ward and in order that exposures should be as short as possible a four-valve transformer, capable of an output of 400 milliamperes at 85 KV., was installed. A tube stand was built for the work, which would give a tube-film distance of 6½ feet above the beds. With this apparatus the exposures varied from 0·02 second for a child, to 0·1 second or a little over for an adult. The bed, which was on castors, was wheeled beneath the tube stand, and the exposures were made, with almost no disturbance of the patient. Radiograms were taken every second or third day. The tube was centred in the supine position at the level of the third costal cartilage.

Radiographic Characteristics

In order to appreciate the varying appearances in lobar pneumonia—and these depend largely on the lobe involved—one has to visualise the location and direction of the interlobar fissures (see accompanying diagrams). The two drawings on the left show the lung as seen in the antero-posterior and postero-anterior planes; those on the right show the lateral

aspect of the lobes. The diagram of the right lung illustrates that the upper lobe presents prominently on the anterior chest wall, while the lower lobe is mainly in contact with the posterior chest wall. The middle lobe is wedge-shaped, and does not come in contact with the posterior wall, its farthest point posteriorly being the hilum, where the interlobar pleura divides (Fig. I. on Plate). On the left side the upper lobe corresponds to the upper and middle lobes of the right.

Consolidation in lobar pneumonia takes place very rapidly as judged by radiograms; for characteristic appearances are usually well marked throughout the entire lobe within twenty-four hours of the onset. The opacity of a pneumonic lobe, as seen in the antero-posterior view, is not homogeneous except where consolidation is so intense as to allow no radiographic differentiation in density. The reason for this is obvious from a study of the diagram—namely, that the lobe is wedge-shaped and the density of its shadow consequently diminishes towards the apex. Unless this important fact is borne in mind, an erroneous interpretation may be made. For example, pneumonia confined to the left lower lobe might be interpreted as also involving the base of the left upper lobe (Figs. II.A and II.B).

Mistakes can always be avoided by taking a lateral radiogram, which shows the exact outline of the involved area. Consolidation in the right upper lobe shows a sharply define lower border, and for the same topographical reason middle lobe consolidation shows a sharply defined upper border. The lower border of a middle lobe pneumonia and the upper part of a lower lobe pneumonia show a shading-off in density. Middle lobe consolidation is easily distinguishable in the lateral radiogram because the consolidation is situated anteriorly, while in the antero-posterior plane there is aeration of the costophrenic angle, unless the lower lobe is also involved. Right lower lobe consolidation extends upwards to the third interspace behind; and unless a lateral view is taken, it may be thought that the middle lobe and part of the upper lobe are also involved. Here also the gradual shading-off of the density in an upward direction helps to prevent mistakes. In the left lung, lower lobe involvement gives a shadow similar to lower lobe involvement on the right side. Consolidation of the left upper lobe lacks the sharp lower border of right upper lobe consolidation; and instead there is a hazy lower border, gradually diminishing in density.

THE EARLY STAGES OF PNEUMONIA

Most pneumonia patients are admitted to hospital late in their illness. Ours were no exception and only a comparatively small proportion were observed in the early stages. Nevertheless 9 were examined within the first forty-eight hours, and 16 within the first seventy-two. In most of these cases the first change noted was an increase in the density and extent of the hilar shadow on the affected side. From the hilum the opacity spreads rapidly towards the periphery, which is the last area to be involved. Even within twenty-four hours of the initial rigor the opacity can be dense and involve a whole lobe without showing any intervening areas of aeration (Figs. III.A and IV.). If the radiogram is slightly overpenetrated and viewed with a strong transmitted light, further details can be seen. Numerous dense thickened "striæ" radiating out from the hilum can be distinguished in the affected region and these are possibly due to the inflammatory engorgement of the vascular and lymphatic tissues.

Coincident with the development of opacity there may be three other changes, but it is hard to say which occurs first, or whether they are simultaneous.

1. The diaphragm on the affected side rises, usually as much as one or two intercostal spaces, regardless of whether a lower or an upper lobe is involved. We have also noticed that sometimes the diaphragm on the unaffected side rises also (Figs. V.A and V.B).

2. The intercostal spaces over the affected lobe or lobes become narrowed.

3. There is occasionally some deflection of the heart and mediastinal structures to the affected side (Fig. VI.). This seems to happen only when the pneumonic process develops very rapidly.

In a few cases—notably in Type III. and Group IV. infections—the X ray appearances in the initial stages are entirely different. Thus the earliest sign may be an opacity at the periphery of the affected lobe and between this opaque area and the hilum there is a zone of normally aerated lung tissue, without any radiological sign of disease. As the disease progresses the consolidation spreads inwards from the opaque area until it reaches the hilum (Figs. XI. and XX.). It is noteworthy that in the peripheral type of pneumonia there may be no definite physical signs until the apex of the opacity has reached the hilum, after which characteristic signs are obtainable.

These two modes of initiation and spread, the "central" and the "peripheral," are quite definite and apparently different. The peripheral spread was in our experience confined to a few cases of Type III. and Group IV. infection.

The opacity increases in density and usually reaches its maximum between the fourth and seventh day; not until resolution begins does it lessen in density. The early appearances have been commented upon by a number of writers. Sante,[25] who has done

GRAHAM HODGSON,
AND WHITBY:

A STUDY OF PNEUMOCOCCAL PNEUMONIA

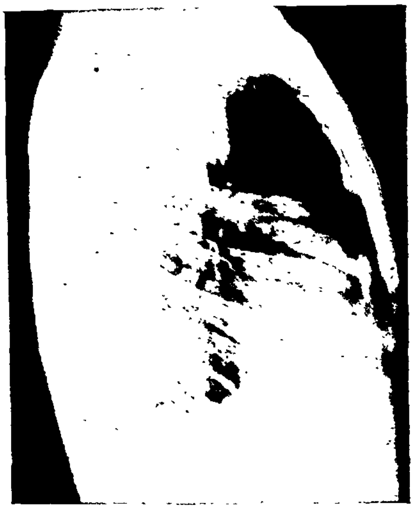

FIG. I.—Lateral view of chest, demonstrating the interlobar fissures of the right lung.

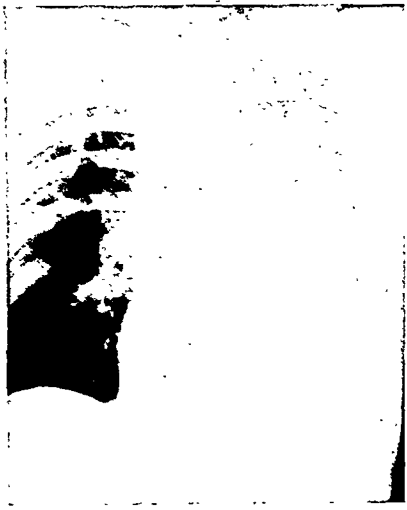

FIG. II.a.—Anteroposterior view, showing opacity of left side of the chest, which might be interpreted as involvement of the lower and upper lobes. 2nd day of disease. (Type I.)

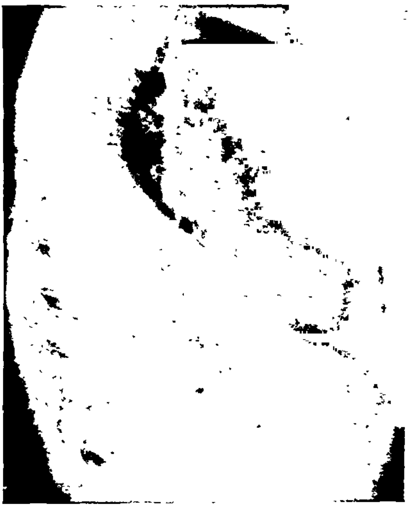

FIG. II.b.—Same case. Lateral view, demonstrating that the opacity is confined to left lower lobe only. 2nd day.

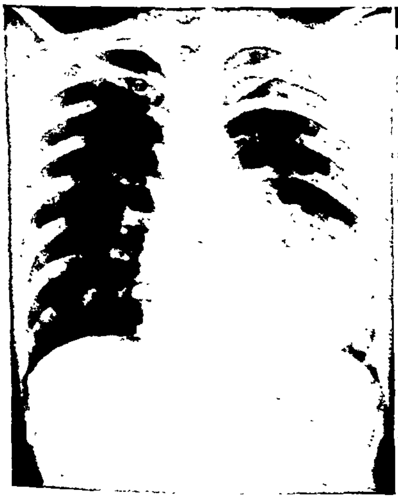

FIG. III.a.—Left lower lobe consolidation, within first 24 hours. (Group IV.)

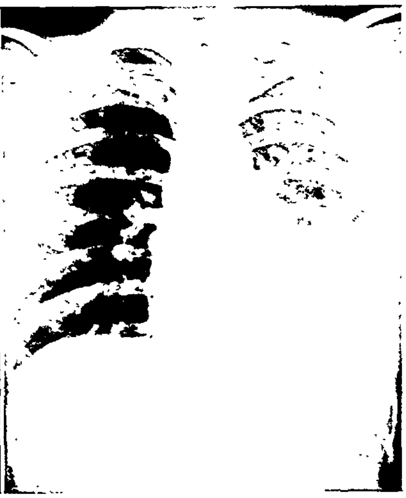

FIG. III.b.—Same case on 23rd day. Hilar glands not enlarged. Delayed resolution.

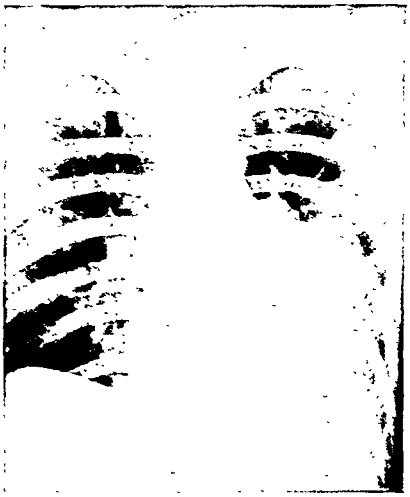

FIG. IV.—Left lower lobe consolidation in first 30 hours. Note the "hazy" opacity spreading to periphery. (Type I.)

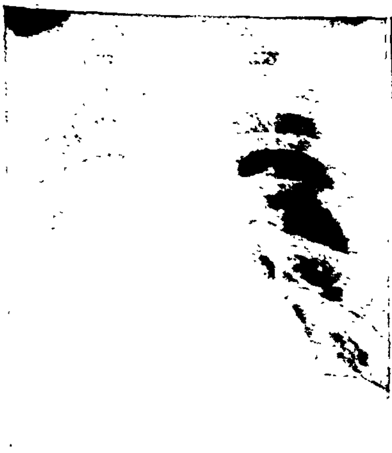

FIG. V.a.—Right lower lobe consolidation with elevation of both diaphragms: right diaphragm at lower border of fourth rib; left at upper border of fifth rib. 4th day of disease. (Group IV.)

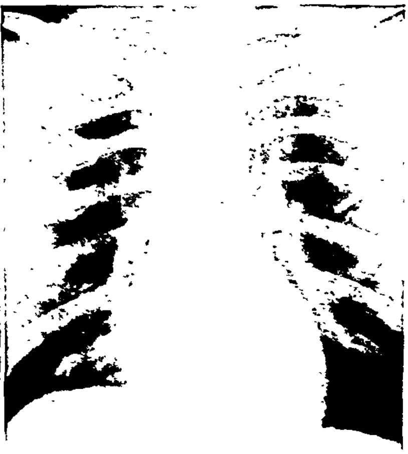

FIG. V.b.—Same case on 35th day. Note level of diaphragm now: right, upper border of sixth rib; left, upper border of seventh.

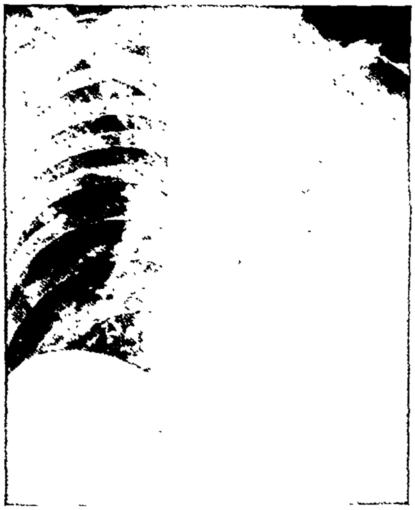

FIG. VI.—Left lung consolidation. 4th day of disease. Trachea and heart displaced to the affected side. (Type I.)

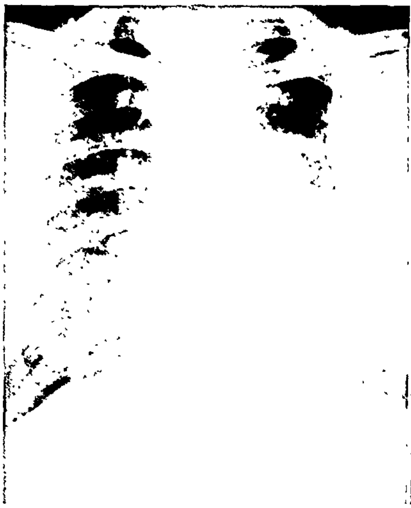

FIG. VII.a.—Left lower lobe consolidation within 24 hours of onset. Opacity spreading towards the periphery. (Type I.)

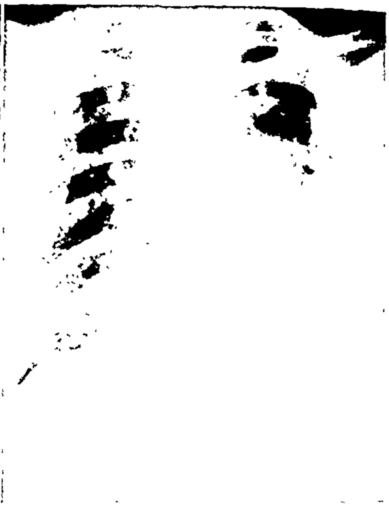

FIG. VII.b.—Same case on 9th day. Crisis on 3rd day under serum treatment but progressive consolidation up to 9th.

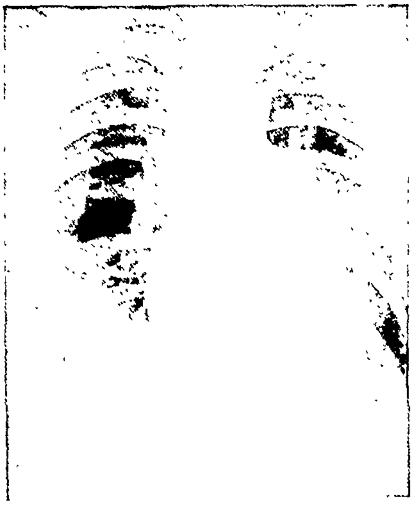

FIG. VIII.—Right lower lobe and left lower lobe consolidation, within first 30 hours. (Type I.)

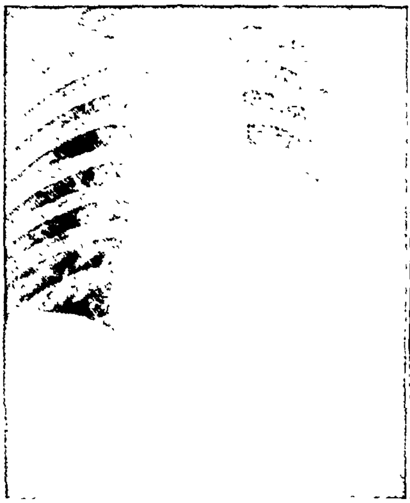

FIG. IX.a.—Left lower lobe consolidation. 6th day. Obvious enlargement of hilar glands. (Type I.)

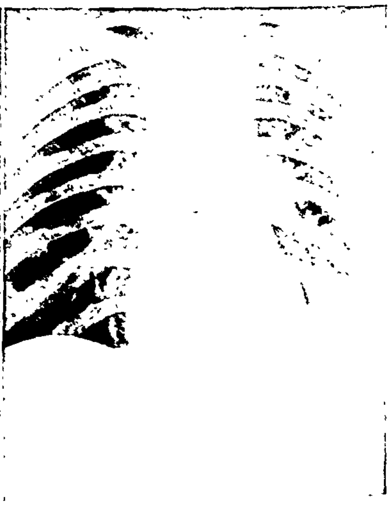

FIG. IX.b.—Same case on 11th day. Rapid resolution. Enlargement of hilar glands. Left diaphragm remains at a high level.

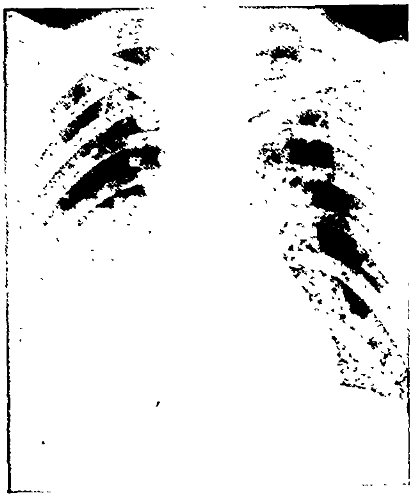

FIG. X.a.—Right lower lobe consolidation. 7th day. No evidence of effusion. Right diaphragm at fourth rib. (Type I.)

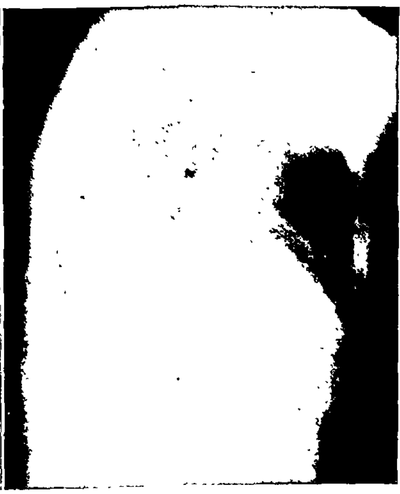

FIG. X.b.—Same case on same day. Lateral view, showing no effusion.

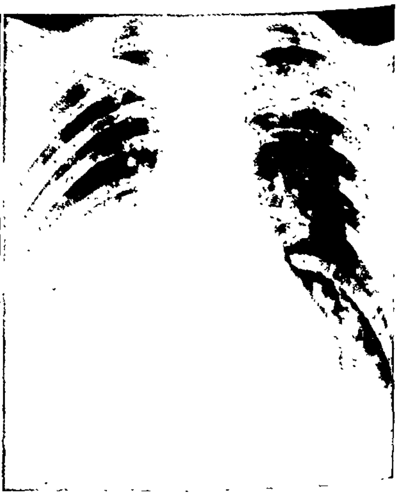

FIG. X.c.—Same case on 11th day. Still no evidence of effusion. Clinical signs suggested early empyema and pus was aspirated on the 12th day. Rib-resection eventually necessary.

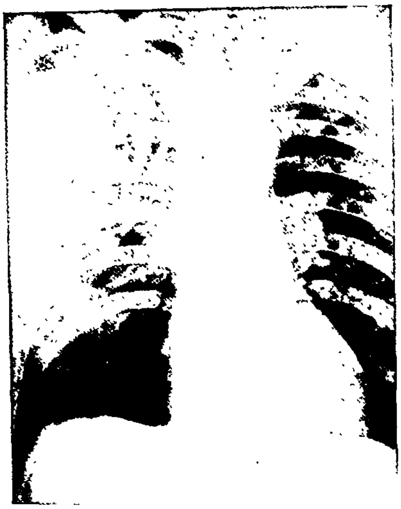

FIG. XI.—Right upper lobe consolidation. 3rd day. Peripheral type of distribution. (Group IV.)

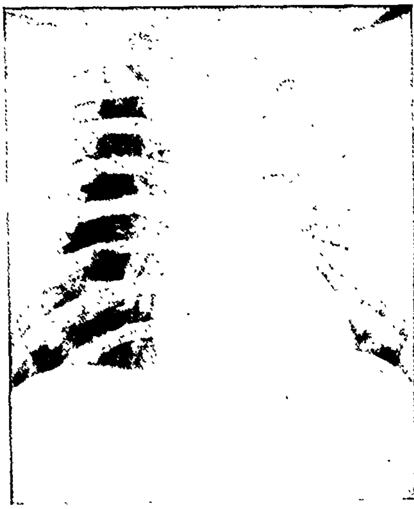

FIG. XII.a.—Left upper lobe consolidation. 7th day. "Hazy" opacity. (Type I.)

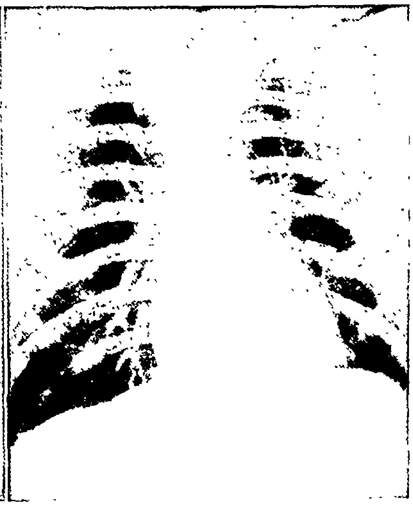

FIG. XII.b.—Same case on 14th day. Almost complete resolution.

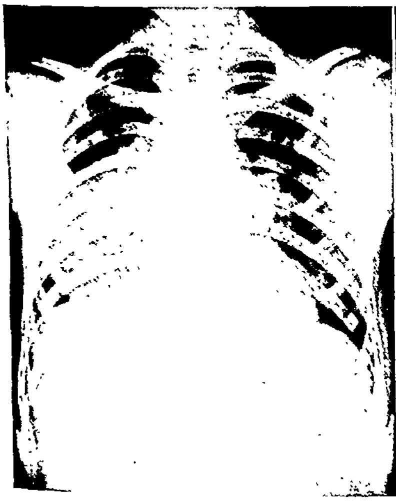

FIG. XIII.a.—Right lower lobe consolidation. 4th day. Note left hilar shadow enlargement. Right diaphragm at fifth rib. (Type I.)

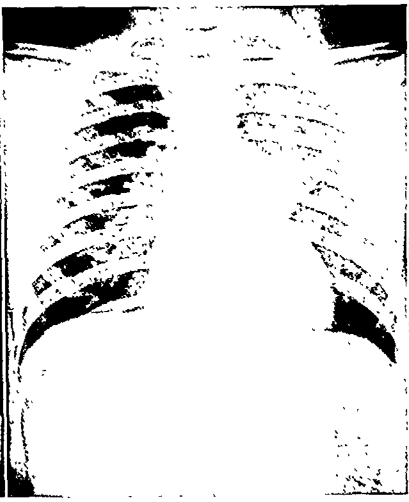

FIG. XIII.b.—Same case on 16th day. Right base cleared completely. Left hilar shadow extending. Clinical signs now apparent over this area. No constitutional symptoms. Right diaphragm at sixth rib.

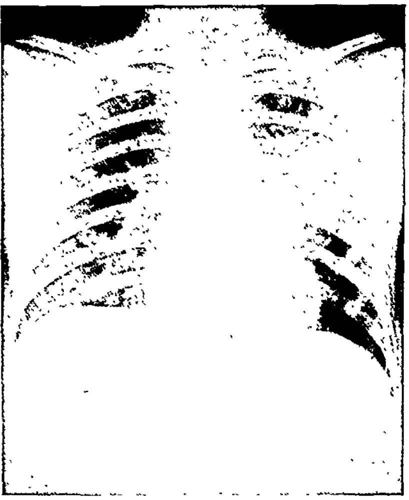

FIG. XIII.c.—Same case on 28th day. Left hilar shadow has extended to involve a large portion of lung. Right diaphragm still at sixth rib.

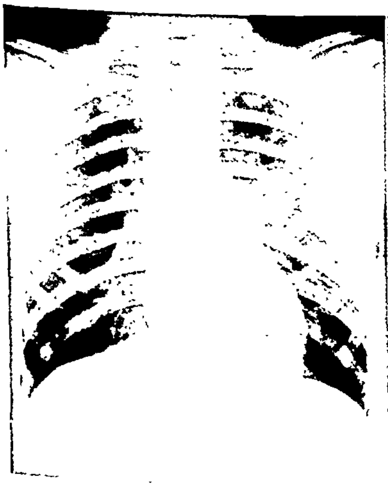

FIG. XIII.d.—Same case on 170th day. Left hilar shadow. Slow resolution. Right diaphragm at seventh rib.

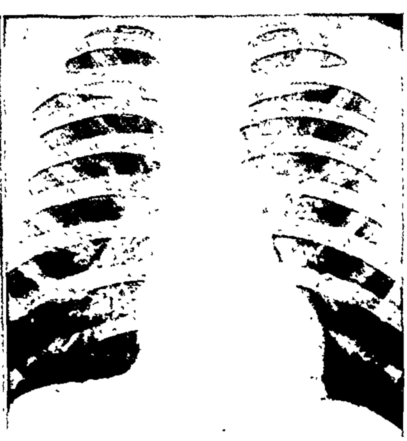

FIG. XIII.e.—Same case two years later. Showing post-pneumonic fibrosis in area previously the seat of slow resolution. Rt. diaphragm at seventh

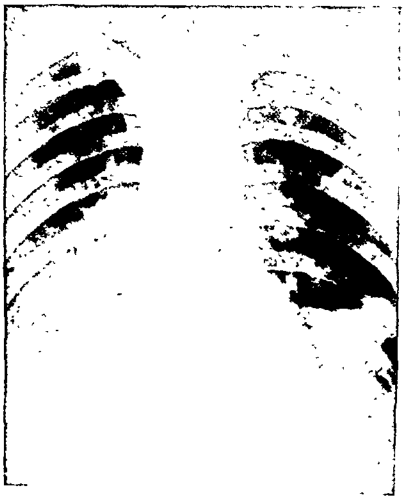

FIG. XIV.—Right lower lobe pneumonia, serum-treated, 2nd day. Small area of consolidation left base, undetected

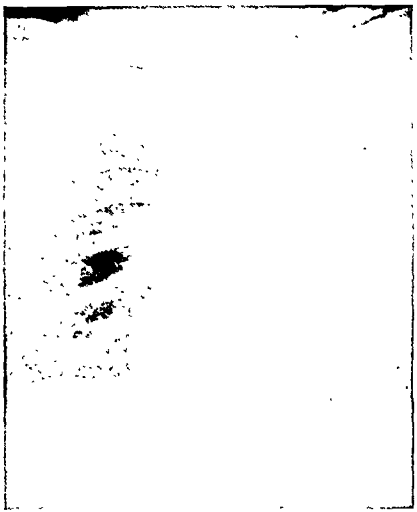

FIG. XV.—Lower lobe and upper lobe consolidation, left side. 15th day. Upper lobe consolidation not detected clinically. (Type I.)

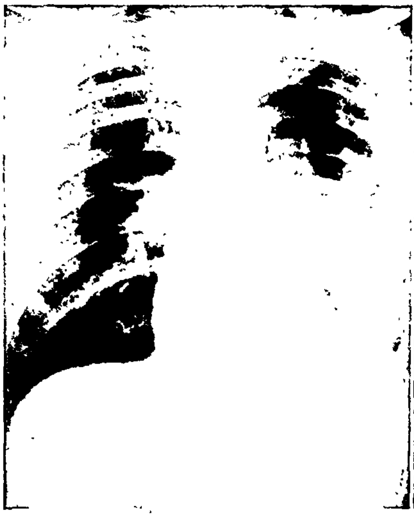

FIG. XVI.a.—Left lower lobe consolidation. 4th day. Calcified glands in both roots. (Type I.)

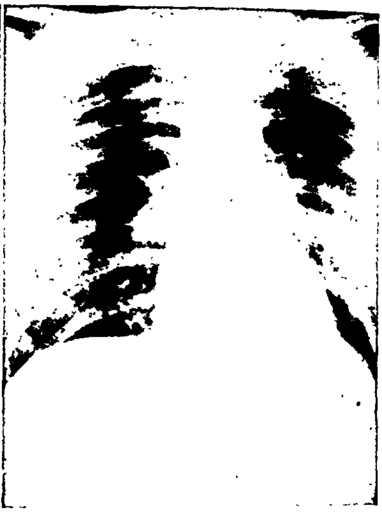

FIG. XVI.b.—Same case on 81st day. Delayed resolution. Calcified glands in roots.

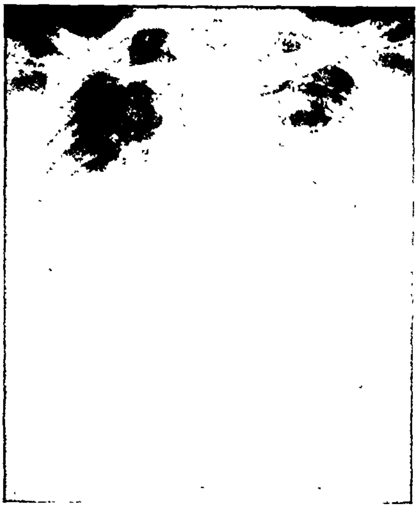

FIG. XVII.—Massive consolidation of both lower lobes. 7th day. Death on 10th day. (Type I.)

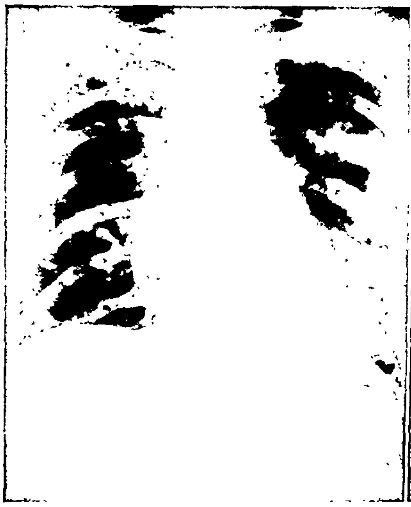

FIG. XVIII.a.—Group IV. pneumonia. 8th day. Scattered areas of consolidation in right upper lobe, right and left lower lobe. Appearances resembling "cavity" in right lower lobe.

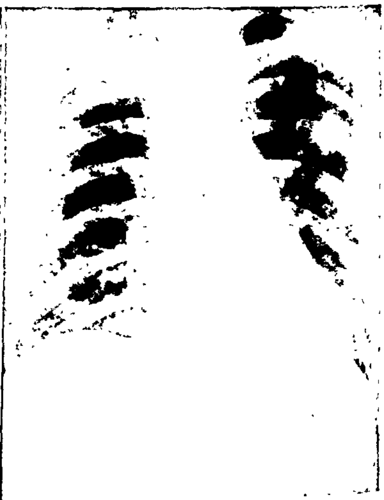

FIG. XVIII.b.—Same case on 55th day. Areas of consolidation still present. "Cavity" in right lower lobe can hardly be distinguished.

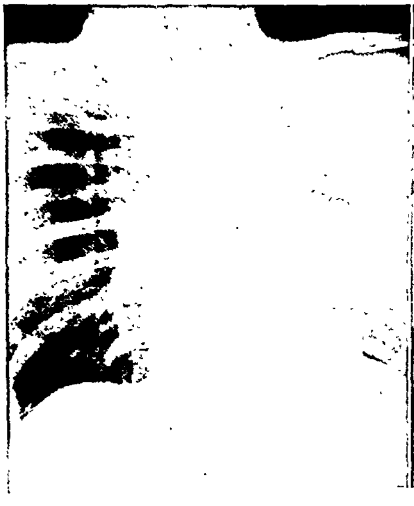

FIG. XIX.a.—Group IV. pneumonia. 18th day. Scattered areas of consolidation in left lung. "Cavity" in left upper zone barely perceptible.

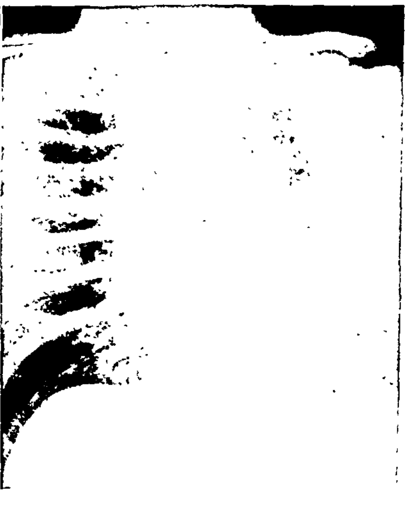

FIG. XIX.b.—Same case on 33rd day. "Cavity" in left zone more conspicuous.

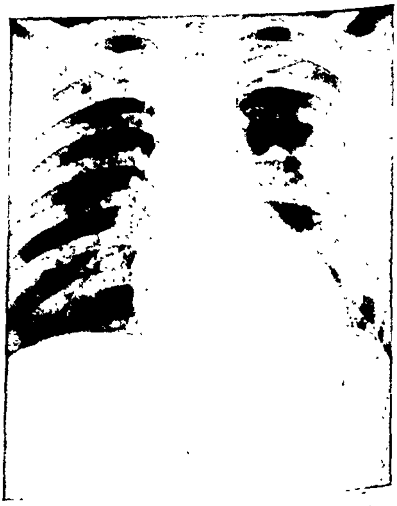

FIG. XX.—Left lower lobe. Peripheral form of consolidation. Atypical clinical signs. (Type III.)

much work on the subject, found dense consolidation within the first twenty-four hours and maintained that the central mode of spread is by far the commoner. This view has been criticised by others but our results confirm it. Mason [26] and Weill and Mouriquand [27] state that in children (in whom a Type I. or II. infection is rare) the peripheral form of spread is more usual.

The rapidity of consolidation is remarkable. Terrell, Robertson, and Coggeshall [28] in an experimental study of pneumonia in dogs found it well advanced within the first day, and also noted elevation of the diaphragm. In 42 dogs out of 105 definite mediastinal displacement was recorded; where the pneumonic process spread slowly there was little, but when the lobe or lobes were rapidly consolidated some shift was clearly demonstrable.

DOES THE LOBE COLLAPSE?

The recognition of rapid consolidation by means of X rays may throw some light on the mechanism by which it takes place. There are two possible processes: it may be due to spread of the infection from the hilum through the interstitial lung tissue around the vessels and branches of the bronchi, or it may depend on some degree of lobar collapse with infection spreading through the portion thus altered. In support of the latter alternative we found elevation of the diaphragm on the affected side, as well as narrowing of the intercostal spaces, whilst in one case there was a shift of the mediastinal structures. Coryllos and Birnbaum [29] in 1929 drew attention to the similarity between atelectasis and lobar pneumonia, and were led to believe that the two conditions were secondary to obstruction of a large bronchus, the obstruction causing atelectasis, circulatory changes, and pulmonary cellulitis. Their investigations included direct observation by bronchoscopy, and they found that the bronchus was frequently blocked. There is therefore some support for Meltzer's view,[30] expressed in 1914, that "the mere presence of pneumococci in the bronchi is not sufficient to produce a pneumococcal infection, but if a previous cold furnishes the mucous secretion which might occlude several small bronchi the ground is prepared for pneumonia." It must be added, however, that Terrell, Robertson, and Coggeshall did not find mucous plugs in the bronchi of experimental pneumonic dogs until quite late in the disease.

Graeser, Wu, and Robertson [31] lately recorded unmistakable radiological signs of pneumonia in 14 patients within thirty hours of the onset of the pneumonia. Furthermore, they found elevation of the diaphragm on the side of the lesion in 18 out of 29 cases, with mediastinal displacement in 3 out of 40. They also comment upon the rarity of peripheral spread—which was seen in only 2 of the 40 cases.

The evidence is somewhat contradictory, and it remains uncertain how large a part collapse plays in the initiation of the pneumonic process. It is indeed quite possible that there is considerable variation; thus in cases showing very rapid consolidation there may be some associated atelectasis secondary to an accident such as the blockage of a reasonably sized bronchus by a plug of mucus, while in cases with a slower spread the process may be purely inflammatory.

Type I. Pneumococcal Pneumonia

Type I. pneumonia is the classical variety: it is sudden in onset and the physical signs during the illness are usually well defined. It is not surprising therefore that the X ray appearances are also distinct and uniform. Of our own Type I. cases 37 were followed through the infection, and we hope to show close agreement between the clinical and radiological signs, noting also the occasions on which added information was obtained by radiography.

It will be convenient to consider separately those which had no specific treatment (18) and those which had Felton's serum (19).

UNTREATED WITH SERUM

Early signs.—Of this group 2 were radiographed within thirty hours of the onset (Fig. VIII.), and it is interesting to record that in both of them X rays showed consolidation on both sides of the chest, whereas clinical examination had suggested that only one lung was involved.

The *established consolidation.*—The opacity spreads outwards from the hilum, involving the periphery last, and varies in density from hazy to dense. We have used the term "hazy" when the line of the diaphragm could be seen and "dense" when it could not. Of the 18 patients only 4 gave hazy shadows; in 2 of these no physical signs could be detected and in the other 2 they were not characteristic of consolidation. In the 14 in whom the opacity was dense the X ray and clinical findings corresponded closely. In 4 of these, however, radiography showed more extensive disease than was indicated by clinical signs. It was somewhat surprising to find that in only 8 out of the 18 was the pneumonia confined to one lobe, although clinically there were only 2 with definite signs that more than one lobe was involved. Consolidation was maximal on the seventh to eighth day. The average day of crisis was the eighth.

Resolution.—As soon as resolution begins—and not before—the hilar glands on both the affected and unaffected sides show obvious enlargement (Figs. IX.A and IX.B). Accordingly, when a case is radiographed some ten days after the onset it is possible to give an opinion whether resolution has or has not begun. The glandular enlargement which takes place during resolution is quite unlike the enlargement due to old pulmonary disease, where the glands are irregular in outline; here they are globular and appear swollen. The time required for complete resolution is very variable. Some lobes have appeared normal 10–14 days after the onset, while others have shown a delay up to the fiftieth. The average for our untreated Type I. group was 20 days from the beginning of the illness. The rate of resolution presumably depends on the extent of the consolidation and its density. Our experience is that enlarged hilar glands are associated with rapid resolution, whereas calcified glands—the result of past disease—are usually associated with some delay. This will be evident from our description of other Type infections.

Complications.—Two patients who developed empyema showed dense consolidation from the outset. Clinical signs were more reliable than the X ray appearances in revealing this complication (Figs. X.A, X.B, and X.C). It would be irrational to expect radiography to disclose a small layer of pus in an area already opaque through consolidation.

Severity of illness.—Although there were exceptions, we came to regard a dense consolidation as being usually associated with severe constitutional symptoms; a hazy opacity on the other hand was characteristic of the milder forms of pneumonia. Of our 18 cases 8 were classified as mild, and of these 4 showed hazy opacities. The milder the case the more rapid the resolution. An example of this is seen in Figs. XII.A and XII.B, illustrating a case in which clinical signs were indefinite; X ray examination showed a hazy opacity in the left upper lobe, the crisis occurred on the fourth day and radiological signs of abnormality had almost disappeared from the lung by the fourteenth (Fig. XII.B).

Extension of consolidation.—Only one case in the Type I. group showed an extension of the pneumonic process (Fig. XIII.A–E). Despite an early crisis on the fourth day the initial consolidation in the right lower lobe was slow in clearing, and there was much enlargement of hilar glands. From the fifteenth day onwards there was a gradual extension of the left hilar shadow which ultimately involved the whole of the left upper lobe. This gave typical physical signs four days after it was first noted on the X ray films. While the initial consolidation was resolving this shadow extended, and it remained persistent for some considerable time. The patient was radiographed as late as the 170th day, and even then some shadowing was still present. We have observed that while a rapidly forming consolidation often as rapidly disappears, a slowly forming one frequently ends in delayed resolution and sometimes permanent fibrosis.

SERUM-TREATED CASES

Early signs.—Of the 19 in this group 5 were radiographed within forty-eight hours of the onset. In all 5 a definite opacity was seen spreading from the hilum to a lower lobe. The physical signs were equally clear and no difficulty was experienced clinically in outlining the lobe involved, although in one case a smaller area of consolidation on the opposite side was only detected radiologically at that time (Fig. XIV.).

Established consolidation.—Dense opacities were observed in 14 of the cases at the height of the illness, while the other 5 showed only a hazy consolidation and atypical physical signs. In 5 cases the clinical signs did not indicate the full extent of the lung involvement, and it is important to note that in 4 of these it was an upper lobe consolidation that was missed (Fig. XV.). The physical signs of upper lobe pneumonia are, in fact, surprisingly few—as Graeser, Wu, and Robertson have already remarked.

The effect of serum treatment is to shorten the febrile period and induce an early crisis, but no material hastening of resolution was observed in our cases. Indeed, some with few signs of consolidation when serum treatment started on the first day showed progressive consolidation despite an early crisis on the third day (Figs. VII.A and VII.B). The average day of crisis in the first 10 cases which were treated in the second and third day of their illness was the fourth to fifth, whereas the clinical and X ray signs reached their maximum on the seventh. Although the number of our cases is small, we feel justified in stating that, in spite of the dramatic relief afforded by serotherapy, it has no demonstrable local effect on the consolidation.

Resolution.—The most rapid resolution was in a patient treated with serum on the second day. The crisis was on the third, and no radiological signs could be seen on the seventh. In 4 which showed long delayed resolution—up to the ninetieth, fifty-ninth, fifty-first, and thirtieth days—calcification of the hilar glands was present. Of these patients 9 suffered from chronic chest disease, and the average day of complete radiological resolution among them was the thirty-first from the onset of the illness (Figs. XVI.A and XVI.B). In contrast, 7 patients who were previously well and who were free of complications showed complete radiological resolution, on the average, by the fourteenth.

Complications.—There were 3 cases of empyema in this group, and the one which was fatal showed bilateral empyema. In all 3 the consolidation was very dense from the outset.

Extension of consolidation was seen in only one case. The process eventually involved all of both lungs except the right upper lobe (Fig. XVII.)

Type II. Pneumococcal Pneumonia

Type II. pneumonia is more severe than Type I. The toxic pallor and the quiet resignation of the patient contrast forcibly with the high colour and restlessness of Type I. infection. The onset is sudden and the signs of consolidation are usually well defined.

Seven of our patients were studied from the fourth day onwards. The general X ray appearances differed in no way from those seen in Type I., but whereas in the normally progressing Type I. infection the lung cleared up completely, leaving no trace of the inflammation, in Type II. there seemed to be a tendency to a permanent, although slight, increase in the density and extent of the pulmonary striæ.

The relation between clinical and radiological signs was more or less close. The infection was confined to one lobe in 4 of the patients; in the remaining 3 (2 of whom died) two lobes were consolidated. Resolution was complete in a period varying from 12 and 31 days. Enlargement of hilar glands was observed as in Type I.

Type III. Pneumococcal Pneumonia

This form of pneumococcal infection is known to attack the debilitated and aged, and carries a high mortality. The course is often ill-defined, and the onset less sudden than in the types so far considered. Often the signs of consolidation are few. It is not surprising therefore to find that the opacity is unlike that seen in Types I. and II. As a rule it is not homogeneous; frequently it is patchy and generally peripheral in distribution (Fig. XX.). The appearances also differ in that the level of the diaphragm usually remains unchanged. The date of resolution in our series varied between the thirteenth and seventy-second day.

This group, although small, contains most of the features accepted as characteristic of Type III. infections. Of the 12 patients 5 gave a history of chronic bronchitis, and in 3 of these calcification of the hilar glands could be detected. In the cases showing chronic disease of the chest the consolidation was ill-defined and either resolution was delayed or the patient died. In contrast to these older subjects there is another class of patient—younger in years, with better defined consolidation, an early crisis, and more rapid resolution.

It is significant that we have found more disparity between clinical and radiological signs in this group than in any other. No clinical signs were discovered in 4, yet 3 of these showed "hazy" opacities affecting one or more lobes. In only 4 of the 12 was there any close agreement between physical and X ray findings. The reason for this disparity is the absence of any dense consolidation; it is patchy, and more peripheral than central. When a consolidation is lateral and peripheral there is still a good deal of lung surface, both anteriorly and posteriorly, over which a reasonably good note and unaltered breath sounds are audible (Fig. XX.).

Group IV. Pneumococcal Pneumonia

Produced by a variety of non-specific pneumococci, Group IV. pneumonia, although common, is less of a clinical entity than the others. Occasionally the infection is severe, but all grades may be met with, and grading is also evident in the local phenomena; some show well-defined consolidation, while in others there is little evidence of a local lung lesion.

In this group 22 patients were submitted to periodic X ray examination. The opacity as a rule was only moderately dense and the distribution was usually peripheral. In 1 case the appearances closely resembled miliary tuberculosis; in 2 cases large cavities suggestive of tuberculosis appeared and disappeared completely during the illness (Figs. XVIII.A, XVIII.B, XIX.A, and XIX.B). In the majority, the height of the diaphragm remained unchanged. The glands enlarged as resolution commenced, as in the other types. Resolution was complete in some cases as early as the fourteenth day; the average, however, was the thirtieth day.

There was close agreement between clinical and radiological findings when the consolidation was dense, but when it was patchy and hazy the physical signs were as inconclusive as in Type III. infection. In 12 of the cases consolidation was hazy, while 6 showed more extensive radiological signs of involvement than was suggested by clinical examination.

In some of this group resolution was extremely rapid. One patient, a man aged 20, who showed a crisis on the fourth day, had considerable enlargement of the hilar glands, and resolution was complete by the eleventh day. In 6 in whom the hilar glands were greatly enlarged resolution was complete by the fourteenth. On the other hand, resolution was not complete until the thirty-sixth day in a young woman aged 20, and the only apparent explanation of the delay was the absence of any hilar enlargement (Figs. III.A and III.B).

Empyema developed in 2 of this group, and in both of them pus was aspirated on clinical evidence before any change could be seen in the X ray films.

The Heart in Pneumonia

Frequent radiography enabled us to keep close watch for changes in the heart during the illness, but in our whole series of 119 we found only 3 patients in whom there was any definite change in its size. Some films showed a prominent pulmonary cone, but we do not consider this change significant.

We believe that cardiac enlargement during pneumonia is rare, but when it occurs it must be recognised as a sign of myocardial damage, even if only temporary. The three cases deserve a brief description.

1. A boy aged 15, suffering from a Type I. infection with a left lower lobe consolidation. He showed high fever and a respiratory rate of over 40, but his pulse-rate never exceeded 80. The pulse was dicrotic in character, and the blood pressure 80/50. The pulse-rate fell to 50 on the seventh day and gradually quickened to 70 on the fourteenth. The B.P. also rose to 115/70 when convalescence was established. During the acute phase of the illness it was recognised that the boy was in a very toxic state, and he also showed an absence of leucocytosis. His transverse cardiac measurements were:

Day.	Cm.	Day.	Cm.
5th	11	10th	14·5
7th	14	14th	11

2. A man aged 37, with a Type I. infection of the left lower lobe. He was admitted on the seventh day of his illness with a temperature of 102·4° F., a pulse of 128, and a respiratory rate of 36. The blood pressure was 98/70. He was not seriously ill. Crisis occurred on the eighth day and recovery was apparently rapid. The pulse, however, fell rapidly. It registered 60 on the ninth day, 52 on the fourteenth, and 50 on the seventeenth. The cardiac measurements were:

Day.	Cm.	Day.	Cm.
7th	14·6	14th	13·5
9th	14·0	19th	12·7

3. A man aged 25, with a Type I. infection involving the right lower lobe and left base, severely ill and treated with Felton's serum. Crisis occurred on the fourth day. On admission on his first day of disease the temperature was 104·6° F., the pulse 140, and respiratory rate 40. The blood pressure fell to 88/60 on the fourth day, to rise to 110/80 following the crisis. The pulse was 80 on the fifth day, and records between 50 and 60 were obtained during the following ten days. The cardiac measurements were:

Day.	Cm.	Day.	Cm.
2nd	14·2	15th	14·7
4th	15·7	21st	14·5
6th	16·0	24th	12·9
8th	15·2		

These were moderately severe cases of pneumonia and they had no clinical *symptoms* suggestive of cardiac disability. In all three, however, there was a relative bradycardia—in one at the height of the fever, and in the other two following the crisis—and in all three a systolic pressure below 100 was recorded. The increase in cardiac diameter was 3·5, 1·9, and 3·1 cm. respectively.

Levy[32] in 1923 found that the heart shadow enlarged during convalescence in two of his pneumonia patients; these were also examples of pronounced post-febrile bradycardia. These findings suggest "that bradycardia under these conditions is a sign of cardiac exhaustion, even though the rhythm is normal" (Levy). We have since observed this condition in another patient who remained very listless and ill for four days after a pneumonic crisis. There was nothing in the lungs to suggest a cause for the symptoms, but we recognised the potential danger of a post-febrile bradycardia (56) and a blood pressure of 90/60. With "absolute" rest the patient made a gradual recovery.

From these few examples we deduce that bradycardia during or following pneumonia is suggestive of some myocardial involvement; and if this finding is accompanied by a systolic blood pressure below 100, it should be a warning of the necessity for the utmost caution. This is probably the type of patient who (rarely, it is true) dies tragically and suddenly when allowed up too soon during convalescence.

General Discussion

The important questions for discussion are: (1) Does radiology throw any light on the development of the pneumonic lesion? and (2) Is it of practical assistance in diagnosis and treatment?

There is little doubt that the central mode of spread—i.e., a rapid extension of consolidation from the hilum—is the commoner form of the pneumonic process, and in pneumonia of Types I. and II. it was certainly the usual one. On the other hand, in Type III. and Group IV. infections a peripheral focus with subsequent extension towards the hilum was not uncommon.

The rapidity with which a lobe becomes consolidated can be appreciated with the help of radiology. Thus a radiogram taken on the second day of the disease sometimes shows a dense shadow occupying the position of a whole lobe; and Terrell, Robertson, and

Coggeshall investigating experimental pneumonia in dogs found dense consolidations even within the first twenty-four hours. It is indeed difficult to obtain a large collection of clinical material demonstrating the very earliest changes. In the dog it has been noted that when consolidation progresses rapidly there is usually some mediastinal displacement. We found one such case in our human series whilst Graeser, Wu, and Robertson record 3 in a series of 40. Narrowing of the intercostal spaces and a elevation of the diaphragm are commonly seen when there is dense consolidation, and these findings suggest that some degree of lobar collapse, in addition to an acute infection, plays a part in forming the picture we know as lobar pneumonia. The quicker the consolidation the more likely is lobar collapse. Unfortunately our observations do not provide absolute evidence of such collapse; but we are satisfied from the indirect evidence described above that it is operative in certain cases. It is hard to see why infection should so often be limited to a single lobe unless there is some mechanical factor which suddenly makes it vulnerable.

It is sometimes important to make a diagnosis of lobar pneumonia with the utmost speed. A patient with high fever may show inconclusive local physical signs, and if serum treatment is contemplated a decision must be reached at once. Radiography 24–48 hours after the onset should show unmistakable signs if pneumonia is present.

Under various headings we have shown that the consolidation seen with X rays is often more extensive than would be supposed from the physical signs. At post-mortem, too, it is usually well in advance of bedside prophecy. An upper lobe consolidation seems to be the most elusive, and in many of our patients radiography showed lesions in this situation of which there was little evidence clinically. We have also been impressed with the frequency of pneumonia affecting more than one lobe: thus in our Type I. series 16 out of 37 showed abnormality in an adjacent lobe or in the opposite lung, although in only 3 of them we had been able to find signs of more than one lobe being involved. It must be admitted that more than half these 16 cases showed radiological lesions of only portions of other lobes, and there is no doubt that where consolidation is well established and shows on a film as a dense discrete shadow, physical examination is as capable as X rays of delineating the outline of the lobe; small extensions and early extensions, however, are far more easily and accurately discovered by radiography than by clinical methods.

Types I. and II. infection proved the most uniform in their lobar distribution and usually furnished a dense opacity. The greatest variation in spread and density was encountered in Type III. and Group IV. infections. The peripheral form of consolidation, especially in its earliest stages, was associated with indefinite and inconclusive physical signs, and our clinical assessment of the extent and locality of the infection is seen to be especially poor—and inferior to radiography—in Type III. pneumonia. As Mason has pointed out, signs may be absent in "peripheral" consolidation until it has extended to the hilar region.

The rate of resolution of consolidated lung varies considerably; in some patients the lung is normal to all appearances as early as the fourteenth day, whereas in some there is delay up to the fiftieth. In our cases resolution was ordinarily complete by the twentieth day, but generally speaking the older the patient the slower was the process of clearing. In multilobed infections one lobe might be showing rapid resolution while another showed increasing consolidation. Enlargement of the hilar glands was commonly associated with rapid resolution; calcified glands, on the other hand, often meant delay.

The opacity of the consolidated lobe begins to clear at the periphery, and the process gradually extends inwards until the last portion near the hilum becomes translucent. In the course of resolution many peculiar pictures may be obtained: several of our patients showed small "cavities," which gradually thinned out and eventually disappeared, and false deductions might quite easily have been drawn if single films had been taken. It is interesting to note that Terrell, Robertson, and Coggeshall found similar "cavities" in the resolving lung of the dog; they were able to show that these were due to dilated atria or air sacs—the dilatations tending to persist longer than the other changes in the consolidated lung.

In the early diagnosis of empyema radiological signs are inferior to physical signs, and in three of our cases pus was aspirated from the pleural cavity on clinical grounds before any change was demonstrable in the X ray films. In our cases empyema was always a sequel to consolidation so dense as to be unaltered by the presence of a thin layer of pus in the pleural cavity.

Cardiac enlargement has been found as a complication of only 3 cases, and in all of these it was accompanied by a relative bradycardia, a sign which fortunately is easily recognised.

The effect of serum treatment was closely observed, but we are unable to show any "abortive effect" on the process of consolidation, even though the constitutional symptoms and signs were greatly reduced, and an early crisis was precipitated. It is, of course, possible that the use of serum prevented further extension of the pneumonia.

We wish to acknowledge our indebtedness to Lord Dawson of Penn and the Royal College of Physicians of London for the facilities and grant enabling us to prosecute this study. We also wish to record our thanks to Sir Frederick Menzies and Sir Thomas Carey Evans for permission to make the investigation at Hammersmith Hospital; to Dr. Arthur Morris, Dr. Bevan Jones, Dr. F. T. J. Hobday, and Dr. C. D. Porter for their active and willing coöperation; to Dr. F. Lee Lander and Dr. Ursula Shelley for assistance in analysing the records kindly supplied by the Middlesex and Royal Free Hospitals; to Mr. S. R. M. Busby, senior technician of the Bland-Sutton Institute, for his ready help at all hours of the day or night; to Dr. Stanley White, of Messrs. Parke, Davis and Co., for making possible the purchase of serum; to Dr. R. A. O'Brien and Dr. H. J. Parish, of the Wellcome Research Laboratories, for much advice as well as supplies of material; to Mr. J. M. Kenny and Mr. Stephen Smith, who assisted with the development of the films; to Messrs. Newton and Wright for erecting and lending the necessary X ray apparatus; and to Messrs. Ilford for the reproduction of the films.

HOSPITAL EXTENSION AT BRISTOL.—The Lord Mayor's Hospitals Extension Fund committee at Bristol have started a house-to-house collection in connexion with their efforts to raise £250,000 for alterations and additions to the voluntary hospitals.

EXPERIMENTAL HYPERPLASIA OF THE PROSTATE

By A. S. Parkes, Sc.D., F.R.S.
MEMBER OF THE SCIENTIFIC STAFF OF THE MEDICAL RESEARCH COUNCIL; AND

S. Zuckerman, D.Sc., M.R.C.S. Eng.
BEIT MEMORIAL RESEARCH FELLOW

(From the National Institute for Medical Research, London, and the Department of Human Anatomy, Oxford)

The first knowledge of possible endocrine factors underlying abnormal prostatic enlargement has been provided by recent work on the effects of gonadal hormones on the prostate of rodents. The available data suggest that it is not the male hormone, but the so-called "female sex-hormone" œstrin, which may be concerned in this condition. It has been clearly demonstrated (Lacassagne, 1933) that relatively large amounts of œstrin (500 mouse units per week over periods of five months) will produce considerable growth of the dorsal prostatic lobes of the mouse, and that retention of urine and hydronephrosis develop as a result. The initial response of the mouse prostate to such treatment consists of reduction in the number of glands in the dorsal lobes; the glandular cells do not begin to multiply until about four weeks after the beginning of injections. Cornification later sets in, and the alveolæ become greatly distended with keratinised epithelial debris and leucocytes. Lacassagne's observations have been independently confirmed in detail by Burrows and Kennaway (1934), while David, Freud, and de Jongh (1934), and Korenchevsky and Dennison (1934) have demonstrated an increase in weight of the prostate of the castrated rat as a result of œstrin injection.

Recently we have reported in abstract on changes produced by œstrone in the prostate of the rhesus monkey, *Macaca mulatta*, and the Guinea baboon, *Papio papio* (Parkes and Zuckerman, 1935). Almost simultaneously with this publication of our findings, which are described below in more detail, Courrier and Gros (1935) published a short account of similar observations on the Barbary ape, *Macaca inuus*.* Owing to the anatomical similarity of the monkey and human prostates, a valid comparison can be made of the response of the former to œstrone with the clinical condition of prostatic hypertrophy.

Table I.—*Control Monkeys*

11	3·5	3-3/12	2
17	3·5	3-1/12	2
22	—	2-2/12	2–3
23	1·8	1-8/12	1–2
27	2·7	2-8/12	1–2

MATERIAL

A list of the monkeys used in the present study, together with relevant details, is given in Tables I. and II. Estimates of age are based on body-weight and dentition (Schultz, 1933). All the animals were immature. MM 13 and 22 were Guinea baboons, *Papio papio*, and the remainder were rhesus monkeys, *Macaca mulatta*.

Table II.—*Monkeys Receiving Œstrin*

No.	Weight at start of exper. (kg.).	Approx. age (years).	Days injected.	Total œstrone injected (mg.).	Utricular epithelium (layers).
MM 1	4·3	3-7/12	6	30·0	5–6
12	4·3	4	6	30·0	4–5
13	4·4	2-2/12	6	30·0	8–16
14	3·9	3	6	15·0	2–8
15	4·1	3-1/12	6	30·0	2–3

---

* We are informed, in a personal communication, that similar observations, as yet unpublished, have also been independently made in the United States by Dr. G. van Wagenen.

Coggeshall investigating experimental pneumonia in dogs found dense consolidations even within the first twenty-four hours. It is indeed difficult to obtain a large collection of clinical material demonstrating the very earliest changes. In the dog it has been noted that when consolidation progresses rapidly there is usually some mediastinal displacement. We found one such case in our human series whilst Graeser, Wu, and Robertson record 3 in a series of 40. Narrowing of the intercostal spaces and a elevation of the diaphragm are commonly seen when there is dense consolidation, and these findings suggest that some degree of lobar collapse, in addition to an acute infection, plays a part in forming the picture we know as lobar pneumonia. The quicker the consolidation the more likely is lobar collapse. Unfortunately our observations do not provide absolute evidence of such collapse; but we are satisfied from the indirect evidence described above that it is operative in certain cases. It is hard to see why infection should so often be limited to a single lobe unless there is some mechanical factor which suddenly makes it vulnerable.

It is sometimes important to make a diagnosis of lobar pneumonia with the utmost speed. A patient with high fever may show inconclusive local physical signs, and if serum treatment is contemplated a decision must be reached at once. Radiography 24–48 hours after the onset should show unmistakable signs if pneumonia is present.

Under various headings we have shown that the consolidation seen with X rays is often more extensive than would be supposed from the physical signs. At post-mortem, too, it is usually well in advance of bedside prophecy. An upper lobe consolidation seems to be the most elusive, and in many of our patients radiography showed lesions in this situation of which there was little evidence clinically. We have also been impressed with the frequency of pneumonia affecting more than one lobe: thus in our Type I. series 16 out of 37 showed abnormality in an adjacent lobe or in the opposite lung, although in only 3 of them we had been able to find signs of more than one lobe being involved. It must be admitted that more than half these 16 cases showed radiological lesions of only portions of other lobes, and there is no doubt that where consolidation is well established and shows on a film as a dense discrete shadow, physical examination is as capable as X rays of delineating the outline of the lobe; small extensions and early extensions, however, are far more easily and accurately discovered by radiography than by clinical methods.

Types I. and II. infection proved the most uniform in their lobar distribution and usually furnished a dense opacity. The greatest variation in spread and density was encountered in Type III. and Group IV. infections. The peripheral form of consolidation, especially in its earliest stages, was associated with indefinite and inconclusive physical signs, and our clinical assessment of the extent and locality of the infection is seen to be especially poor—and inferior to radiography—in Type III. pneumonia. As Mason has pointed out, signs may be absent in "peripheral" consolidation until it has extended to the hilar region.

The rate of resolution of consolidated lung varies considerably; in some patients the lung is normal to all appearances as early as the fourteenth day, whereas in some there is delay up to the fiftieth. In our cases resolution was ordinarily complete by the twentieth day, but generally speaking the older the patient the slower was the process of clearing. In multilobed infections one lobe might be showing rapid resolution while another showed increasing consolidation. Enlargement of the hilar glands was commonly associated with rapid resolution; calcified glands, on the other hand, often meant delay.

The opacity of the consolidated lobe begins to clear at the periphery, and the process gradually extends inwards until the last portion near the hilum becomes translucent. In the course of resolution many peculiar pictures may be obtained: several of our patients showed small "cavities," which gradually thinned out and eventually disappeared, and false deductions might quite easily have been drawn if single films had been taken. It is interesting to note that Terrell, Robertson, and Coggeshall found similar "cavities" in the resolving lung of the dog; they were able to show that these were due to dilated atria or air sacs—the dilatations tending to persist longer than the other changes in the consolidated lung.

In the early diagnosis of empyema radiological signs are inferior to physical signs, and in three of our cases pus was aspirated from the pleural cavity on clinical grounds before any change was demonstrable in the X ray films. In our cases empyema was always a sequel to consolidation so dense as to be unaltered by the presence of a thin layer of pus in the pleural cavity.

Cardiac enlargement has been found as a complication of only 3 cases, and in all of these it was accompanied by a relative bradycardia, a sign which fortunately is easily recognised.

The effect of serum treatment was closely observed, but we are unable to show any "abortive effect" on the process of consolidation, even though the constitutional symptoms and signs were greatly reduced, and an early crisis was precipitated. It is, of course, possible that the use of serum prevented further extension of the pneumonia.

We wish to acknowledge our indebtedness to Lord Dawson of Penn and the Royal College of Physicians of London for the facilities and grant enabling us to prosecute this study. We also wish to record our thanks to Sir Frederick Menzies and Sir Thomas Carey Evans for permission to make the investigation at Hammersmith Hospital; to Dr. Arthur Morris, Dr. Bevan Jones, Dr. F. T. J. Hobday, and Dr. C. D. Porter for their active and willing coöperation; to Dr. F. Lee Lander and Dr. Ursula Shelley for assistance in analysing the records kindly supplied by the Middlesex and Royal Free Hospitals; to Mr. S. R. M. Busby, senior technician of the Bland-Sutton Institute, for his ready help at all hours of the day or night; to Dr. Stanley White, of Messrs. Parke, Davis and Co., for making possible the purchase of serum; to Dr. R. A. O'Brien and Dr. H. J. Parish, of the Wellcome Research Laboratories, for much advice as well as supplies of material; to Mr. J. M. Kenny and Mr. Stephen Smith, who assisted with the development of the films; to Messrs. Newton and Wright for erecting and lending the necessary X ray apparatus; and to Messrs. Ilford for the reproduction of the films.

HOSPITAL EXTENSION AT BRISTOL.—The Lord Mayor's Hospitals Extension Fund committee at Bristol have started a house-to-house collection in connexion with their efforts to raise £250,000 for alterations and additions to the voluntary hospitals.

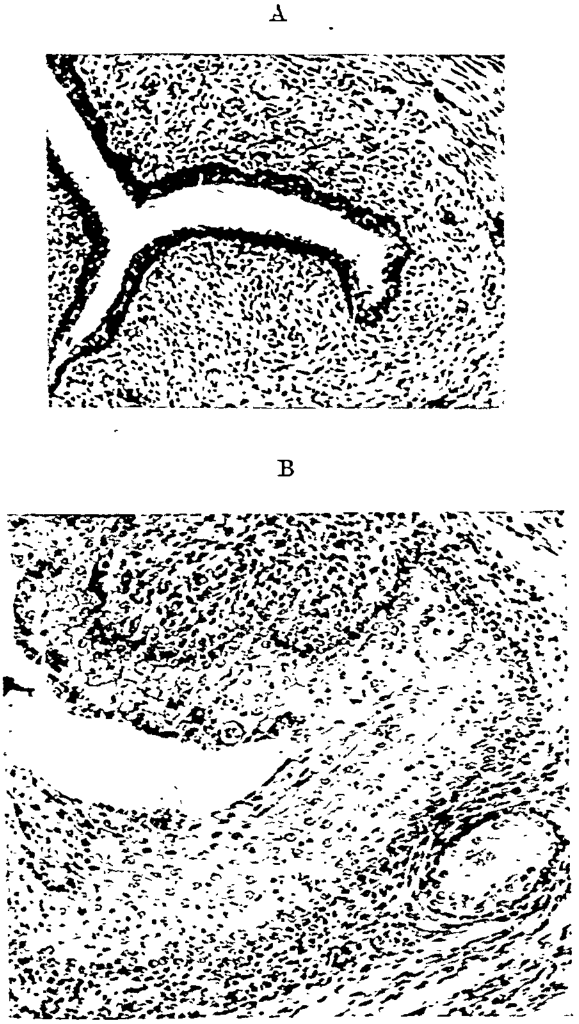

FIG. 3.—(A) Utricle of normal Guinea baboon (MM 22, see Table I.). × 142. (B) Utricle of Guinea baboon after injection of œstrone (MM 13, see Table II.). × 142.

urethra. Irregularities in the utricular epithelium of the rhesus monkey MM 15, suggest incipient "glandular" budding, yet the utricular response of this animal was the poorest in the experimental series. The sensitivity of the animals to œstrone appears to vary greatly, and larger doses do not seem to be necessarily more effective than smaller amounts. Different regions of the utricle also show different degrees of response.

Prostatic glands and stroma.—The prostatic glands are reduced in number in most of the experimental animals, the chief exceptions being the oldest members of the group, MM 18 and 19, in whom they are more or less normal as compared with a control animal of approximately the same age. The glands also tend to be narrower, and they are frequently seen in section as solid cords of cells. The manner in which their number is reduced is by no means clear. The glandular epithelium is generally healthy, and epithelial degeneration was observed in only one case. The narrow glandular lumen in the experimental animals is suggestive of increased stromal pressure, and it seems that the glandular involution may be more apparent than real.

DISCUSSION

The most striking effect of œstrin on the rhesus prostate is the utricular response, which is strictly comparable with the vaginal reaction to œstrin. Since the vagina and uterus masculinus may have a similar embryological origin (Meyer, 1909; Vilas, 1933), and since the utriculus of the rhesus monkey is certainly "vaginal" in appearance, this finding cannot be regarded as surprising. The occasional vestigial remains of a Müllerian duct in male fowls have also been shown to be responsive to œstrin (Juhn and Gustavson, 1932), and it has been argued that the epithelial response to œstrin of the dorsal lobes of the mouse and rat prostate indicates that these lobes, which are usually regarded as being coagulating glands, are also derivatives of the Müllerian ducts (Lacassagne, 1933; Burrows, 1934). Unfortunately embryological evidence on this point is lacking. It may be noted in this connexion that while there is no utriculus masculinus in the adult mouse, such an organ has been described as occurring in the new-born (Hütt, 1926).

The evidence clearly indicates that œstrin is able to exercise a specific epithelial effect on rudimentary structures in the male which are derived from the embryonic uterovaginal canal. The apparent reduction in the number of true prostatic glands, which are derived from the urogenital sinus, and the corresponding increase in the amount of prostatic fibromuscular tissue, which all observers are agreed originates from the musculature of the genital canal and urogenital sinus, may be regarded, in view of Freud's (1933) clear findings, as part of the general effect of œstrin on the smooth muscle of the accessory reproductive organs.

Coagulating glands, such as occur in the mouse and rat, are not represented in man and, therefore, in spite of the superficial similarity of the urogenital effects of œstrin in the male mouse to the clinical syndrome of enlarged prostate in man, the experimental condition in the rodent cannot be expected to shed direct light on the ætiology of the human disease. On the other hand, our findings on the monkey may have some bearing on this problem. A uterus masculinus is present in all men (Vintemberger, 1926), and the human male undoubtedly elaborates and excretes an œstrogenic substance. In the circumstances, it seems likely that the human prostatic utricle must be regarded as a potentially active organ.

Since the utricular response in the rhesus monkey and Guinea baboon is purely vaginal in character, it bears little resemblance to the glandular hypertrophy characteristic of prostatic enlargement in man. The glandular nature and general "uterine" appearance of the utricle in certain other primate species, including man, suggests, however, that in them it may include a uterine as well as a vaginal component, a possibility which can neither be established nor excluded on the available embryological evidence (see Zuckerman and Parkes, 1935). If the utricular glands, where present, are true homologues of uterine glands, their response to the unopposed action of œstrin should be cystic hyperplasia, such as takes place in the female primate in similar circumstances (Kaufmann, 1934; Zuckerman and Morse, 1935). If such a response occurred in the male, the histological appearance would be that of glandular hyperplasia of the prespermatic lobe of the prostate where, according to many investigators, prostatic enlargement may originate (see Marion, 1923). We are at present extending the experiments to species of monkeys in which the utricle is glandular.

Prostatic enlargement in man is essentially a disease of later life. This fact suggests that it may be associated with male hormone deficiency, and that male hormone therapy is indicated. Van Cappellen (1933) claims to have obtained good clinical results from such treatment, while according to David, Freud, and de Jongh, simultaneous administration of male treatment caused œdematous swelling of the external genitalia and surrounding regions (viz., anus, base of tail, lower part of back, posterior aspects of thighs). A detailed account of this external response of the male has recently been given by Bachman, Collip, and Selye (1935). The swelling never became large enough to cause retention of urine. Autopsies were performed one or two days after the last injection.

THE NORMAL MONKEY PROSTATE

The following description of the normal immature rhesus prostate, which in structure is essentially the same as the human, is based on a study of the control series.

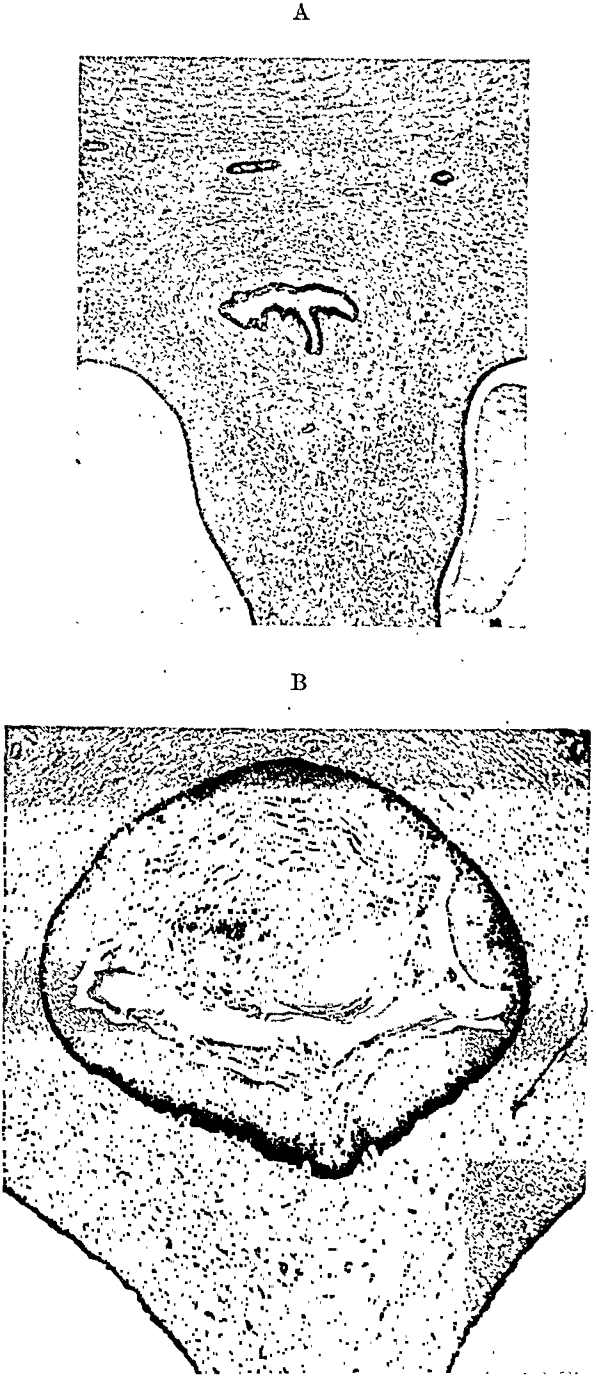

FIG. 2.—(A) Utricle of normal rhesus monkey (MM 11, see Table I.). × 29. (B) Utricle of rhesus monkey after injection of œstrone (MM 18, see Table II.). × 29.

The prostate is a compact glandular organ except in its cranial third, which is broken up into a series of separate lobules, some of which intervene between the muscular coat of the urethra, and the ducts of the seminal vesicles and vasa deferentia. The common ejaculatory ducts are formed about the middle of the cranial half of the prostate, and pass into the urethra on either side of the crista urethralis about the middle of the caudal half of the organ. The utriculus masculinus opens at about the same level. The utricle terminates cranially in the lobulated part of the prostate, and except at its extremities its transverse lumen projects dorsally in the midline in the form of a narrow slit. The prostatic glands do not completely encircle the urethra, as they do in man; the urethra transverses a groove on the ventral surface of the prostate.

The numerous prostatic glands are narrow, tubular, and branched, and lined by a single (occasionally double) layer of columnar cells with relatively large, basal nuclei. The basement membrane is generally well defined. The glands are more widely open, and the epithelium more regular and more obviously secretory, in the older than in the younger specimens. The collecting ducts generally have a double layer of epithelium. Those of the caudal glands ascend, and those of the cranial descend, to open into the urethra near the cranial part of the crista urethralis. They do not open into either the ejaculatory ducts or uterus masculinus, both of which are isolated from the rest of the prostate—and to some extent from each other—by fibromuscular tissue. The glands lie in a stroma of tightly packed collagenous fibres and plain muscle.

The epithelium of the ejaculatory ducts is composed of moderately tall columnar cells, frequently two layers thick, with relatively large nuclei filling the greater part of the cell bodies. In places, where the ducts are distended, the epithelium is much flattened.

The uterus masculinus is lined by low cuboidal epithelium, one to two layers deep in the rhesus monkeys, and two to three in the Guinea baboon. Its lumen is generally small and empty, especially in the dorsal projection, which may be represented by only a cord of epithelium. In specimens MM 2 and MM 9 the utricle contained a homogeneous eosinophil coagulum in which were embedded some cast-off epithelial cells and leucocytes. The stroma of the utricle is less fibrous than that of the rest of the prostate.

EXPERIMENTAL RESULTS

The significant prostatic changes in the experimental animals comprise (*a*) growth of the utricular epithelium and (*b*) reduction in the size and number of the prostatic glands, with a corresponding increase in the amount of collagenous fibrous tissue. Unlike Courrier and Gros (1935), we were unable to detect with certainty any gross enlargement of the prostate as a whole.

Uterus masculinus.—In the animals injected for 6 days the utricle has responded very rapidly to œstrone, the number of layers of epithelium increasing to as many as five times the normal. Mitoses are numerous. The growth is irregular, and the superficial cells are soon shed. Epithelial growth becomes more pronounced as the injections continue, and the basal cells become highly chromophilic like the corresponding cells of the normal vagina. In MM 18 and MM 19 the epithelium is in places as many as 25 layers deep, the more superficial layers being cornified. The lumen of the utricle is distended, appearing circular in cross-section, and is filled with epithelial debris and leucocytes, which can be seen passing through the epithelium from the stroma. The process of distension effaces the normal T-shape of the lumen. The cells surrounding the utriculus appear more numerous and better defined in some of the injected than in the normal monkeys, and there is a suggestion of increased vascularity.

There is a single utricular "gland" in the Guinea baboon, MM 13, but in the absence of adequate control material for this species, it cannot be regarded as an effect of the injections. A presumably specific character exhibited by the Guinea baboon is a very widely dilated prostatic

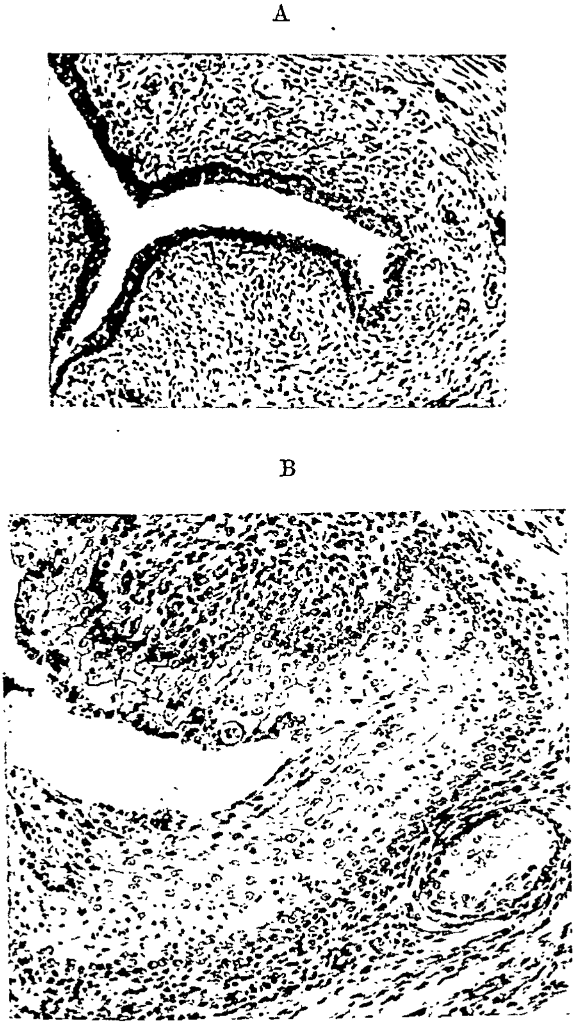

FIG. 3.—(A) Utricle of normal Guinea baboon (MM 22, see Table I.). × 142. (B) Utricle of Guinea baboon after injection of œstrone (MM 13, see Table II.). × 142.

urethra. Irregularities in the utricular epithelium of the rhesus monkey MM 15, suggest incipient "glandular" budding, yet the utricular response of this animal was the poorest in the experimental series. The sensitivity of the animals to œstrone appears to vary greatly, and larger doses do not seem to be necessarily more effective than smaller amounts. Different regions of the utricle also show different degrees of response.

Prostatic glands and stroma.—The prostatic glands are reduced in number in most of the experimental animals, the chief exceptions being the oldest members of the group, MM 18 and 19, in whom they are more or less normal as compared with a control animal of approximately the same age. The glands also tend to be narrower, and they are frequently seen in section as solid cords of cells. The manner in which their number is reduced is by no means clear. The glandular epithelium is generally healthy, and epithelial degeneration was observed in only one case. The narrow glandular lumen in the experimental animals is suggestive of increased stromal pressure, and it seems that the glandular involution may be more apparent than real.

DISCUSSION

The most striking effect of œstrin on the rhesus prostate is the utricular response, which is strictly comparable with the vaginal reaction to œstrin. Since the vagina and uterus masculinus may have a similar embryological origin (Meyer, 1909; Vilas, 1933), and since the utriculus of the rhesus monkey is certainly "vaginal" in appearance, this finding cannot be regarded as surprising. The occasional vestigial remains of a Müllerian duct in male fowls have also been shown to be responsive to œstrin (Juhn and Gustavson, 1932), and it has been argued that the epithelial response to œstrin of the dorsal lobes of the mouse and rat prostate indicates that these lobes, which are usually regarded as being coagulating glands, are also derivatives of the Müllerian ducts (Lacassagne, 1933; Burrows, 1934). Unfortunately embryological evidence on this point is lacking. It may be noted in this connexion that while there is no utriculus masculinus in the adult mouse, such an organ has been described as occurring in the new-born (Hütt, 1926).

The evidence clearly indicates that œstrin is able to exercise a specific epithelial effect on rudimentary structures in the male which are derived from the embryonic uterovaginal canal. The apparent reduction in the number of true prostatic glands, which are derived from the urogenital sinus, and the corresponding increase in the amount of prostatic fibromuscular tissue, which all observers are agreed originates from the musculature of the genital canal and urogenital sinus, may be regarded, in view of Freud's (1933) clear findings, as part of the general effect of œstrin on the smooth muscle of the accessory reproductive organs.

Coagulating glands, such as occur in the mouse and rat, are not represented in man and, therefore, in spite of the superficial similarity of the urogenital effects of œstrin in the male mouse to the clinical syndrome of enlarged prostate in man, the experimental condition in the rodent cannot be expected to shed direct light on the ætiology of the human disease. On the other hand, our findings on the monkey may have some bearing on this problem. A uterus masculinus is present in all men (Vintemberger, 1926), and the human male undoubtedly elaborates and excretes an œstrogenic substance. In the circumstances, it seems likely that the human prostatic utricle must be regarded as a potentially active organ.

Since the utricular response in the rhesus monkey and Guinea baboon is purely vaginal in character, it bears little resemblance to the glandular hypertrophy characteristic of prostatic enlargement in man. The glandular nature and general "uterine" appearance of the utricle in certain other primate species, including man, suggests, however, that in them it may include a uterine as well as a vaginal component, a possibility which can neither be established nor excluded on the available embryological evidence (see Zuckerman and Parkes, 1935). If the utricular glands, where present, are true homologues of uterine glands, their response to the unopposed action of œstrin should be cystic hyperplasia, such as takes place in the female primate in similar circumstances (Kaufmann, 1934; Zuckerman and Morse, 1935). If such a response occurred in the male, the histological appearance would be that of glandular hyperplasia of the prespermatic lobe of the prostate where, according to many investigators, prostatic enlargement may originate (see Marion, 1923). We are at present extending the experiments to species of monkeys in which the utricle is glandular.

Prostatic enlargement in man is essentially a disease of later life. This fact suggests that it may be associated with male hormone deficiency, and that male hormone therapy is indicated. Van Cappellen (1933) claims to have obtained good clinical results from such treatment, while according to David, Freud, and de Jongh, simultaneous administration of male hormone prevents the metaplasia and cornification of the mouse prostate caused by œstrin injection, but it is difficult to understand the mechanism of such a result. If, however, prostatic enlargement in man depends wholly, or in part, on hyperplasia of the utriculus masculinus under the influence of œstrin, there would be other possibilities of therapy. There is good evidence that the effects of œstrin are suppressed by the simultaneous administration of progestin, the hormone of the corpus luteum (Smith and Smith, 1931; Allen and Meyer, 1935). According to Smith and Smith this is due to the fact that progestin stimulates the excretion of œstrin. It is possible, therefore, that the effect of œstrin on the male could be diminished or even prevented altogether by the administration of progestin.

SUMMARY

Ten immature male rhesus monkeys, varying in weight from 1·7 to 4·8 kg., and one immature Guinea baboon, were injected daily, for periods of 6 to 28 days, with an oil solution of œstrone. The total amount injected varied between 1·4 mg. and 30·0 mg. Six normal rhesus monkeys and one Guinea baboon of equivalent weights were used as controls.

The injected series showed pronounced prostatic changes, comprising (*a*) diminution in the number of true prostatic glands, with a corresponding increase in the amount of fibromuscular stroma; and (*b*) epithelial growth in the uterus masculinus. The latter change is very conspicuous, and the utricle acquires a large distended lumen lined by as many as 25 layers of stratified epithelium. The significance of these results to the problem of pathological prostatic enlargement in man is discussed.

The cost of most of the animals was defrayed from a grant to S. Z. from the Medical Research Council.

PUTNEY HOSPITAL.—Prince Arthur of Connaught presided over the annual meeting of Putney Hospital where extensions are to be opened on April 30th by Princess Arthur. Ten new paying wards have been built, the out-patient department has been reconstructed, and a new mortuary and chapel have been given. Offices for the matron and the almoner, a new massage department, a casualty ward, and a suite of rooms for the resident medical officer have also been added.

EMBOLISM OF THE CORONARY ARTERIES

By A. S. Hoseason, M.D., M.R.C.P. Lond.

Coronary embolism is extremely uncommon; the probabilities are so strongly against an embolus of suitable size being swept by the violent aortic stream into a coronary artery that it is remarkable that it should occur at all. The following is an account of a case with references to the scanty literature.

CASE REPORT

The patient, a well-built and muscular male of 36, was brought into hospital one morning at 8.30, having collapsed in the street at 8.15. He said that while proceeding to work and feeling perfectly well he had suddenly been seized with the most intense pain in the chest and across the shoulders. He vomited and collapsed.

Previous history.—About a year before he had been in hospital with cellulitis at the back of the neck, and a little while later with lymphadenitis in that area. He had had no malaise or dyspepsia or definite illness lately; he had in fact been in good health. There was no history of acute rheumatic fever.

Physical examination.—The patient was obviously in considerable pain, but apart from this was not dyspnœic, nor was he cyanosed; there was no smell on the breath. The temperature was 97° F. The only abnormal physical signs were a slow pulse, rate 60, but regular in rhythm and of moderate tension; the area of cardiac dullness extended outwards to the left to the nipple line, and there was a localised systolic murmur in the aortic area. The cardiac impulse was about normal in force, and there were no thrills. There was no abdominal tenderness or rigidity, and examination of the chest and central nervous system was negative. As is said, there were no abnormal signs beyond those described above.

Diagnosis.—It will be seen that tentative theories as to perforation of a peptic ulcer, spontaneous pneumothorax, a tabetic crisis (and even Nothnagel's syndrome) were not supported by the findings. Occlusion of the right coronary artery was suggested, more fancifully than seriously, on the evidence of the pain, the slow pulse, and the lack of any other likely diagnosis.

The patient continued in much the same state up to 9.55 A.M., when he suddenly became blue and died.

Post-mortem.—External appearances were normal except for marked general cyanosis. *Lungs and pleural cavity:* normal. *Pericardial sac:* no excess of pericardial fluid. *Heart:* milk-spots on epicardium. Weight, 14 oz. Left ventricle considerably enlarged (concentric hypertrophy). Right auricle and ventricle and great veins distended with dark, unclotted blood. The myocardium appeared healthy. The aortic valves were sclerosed and partly calcified. The other valves were normal. On the right (posterior) aortic cusp was a small thrombus loosely attached to an ulcerated area over a calcified nodule. Half an inch along the right coronary artery was a small soft clot, about $\frac{1}{3}$ in. long and $\frac{1}{6}$ in. thick—presumably a vegetation derived from the ulcerated valve cusp. *Liver and kidneys:* intensely congested; bladder empty. Pancreas and spleen congested. *Stomach:* mucosa very congested; a small quantity of partly digested food. *Brain:* excess cerebrospinal fluid and slight dilatation of the ventricles.

An interesting contrast was provided by the normality of lungs and the congestion of the other viscera. The explanation lies in the situation of the embolus producing, so to say, an acute "half heart" failure. The distribution of the right coronary artery includes the right auricle, most of the right ventricle, and the posterior part of the interauricular and interventricular septa, where the auriculo-ventricular node is situated, and the bundle of His runs (Walmsley,[1] Gross [2]). The junctional tissues are but poorly vascularised at the best of times, and it has been said

(Gross) that the myocardium of an elderly person is better prepared for coronary occlusion than that of a young man. A sudden failure of the right side of the heart would affect and produce congestion only in the venous circulation and therefore in viscera other than the lungs.

Judging by the sequence of events the obstruction must at first have been incomplete, the embolus probably lying across the mouth of the coronary artery, until at 9.55 A.M. it was forced into the lumen of the artery and the obstruction became complete. The slow pulse was caused by defective conduction in the junctional tissues, probably a 2 : 1 block. An idioventricular rhythm is possible at the high rate of 60, but this is not likely as the man had not fainted (from cerebral anæmia during the pause before his ventricles "took over").

LITERATURE OF THE SUBJECT

The literature of the subject makes interesting reading. O. Saphir[3] collected and analysed the cases known up to 1924, 11 in all, and also gave the details of 3 cases of his own. It appears that Virchow, in 1856, first described coronary embolism in an autopsy on a case of recent endocarditis in a young woman. She had an universal systemic embolism, with several small emboli in her myocardium which, however, were not of any great importance in her general clinical condition. Discussing autopsy reports, Saphir emphasises the point that cases described without evidence of the origin of the embolus should be considered not proven.

After 1924 cases are recorded more frequently.

Jacobi, Kenler, and Silverman[4] had a notable case of paradoxical embolism, in which the patient died 15 minutes after the onset of pain in the chest. An autopsy was performed two hours later, and the following is an extract from their report: "On opening the thoracic cavity, several complete auricular contractions were observed, tapering off into fibrillary twitchings of the left ventricle, while the lungs rapidly deepened in red color and the abdominal veins and pulmonary artery became visibly distended with venous blood." The embolus was found in the left coronary artery, and was derived from a femoral thrombus, having gone through a patent foramen ovale. There was also an infarct in the left kidney, and the lungs, although congested, were not œdematous. It is quite remarkable that the heart of a person (presumably) dead two hours should yet be able to generate beats of a sort. It is of considerable importance to note that a left-sided embolus, causing a failure mainly left ventricular until the heart as a whole became disorganised, should be seen to produce congestion in the lungs, this being in contrast to my case in which the failure was right-sided.

Chevalier Jackson and Babcock[5] reported coronary air embolism during a thoracic operation. The patient died very quickly, and when the heart was looked at bubbles of air were seen in the superficial coronary vessels. They suggest, as a counsel of perfection, that when air embolism occurs, the air should be aspirated with a hypodermic needle and syringe.

The artery most commonly blocked is the anterior descending branch of the left coronary. The embolus is usually a vegetation derived from an ulcerated valve. It is for this reason, as compared with coronary thrombosis, that the victims are relatively young. Death occurs fairly soon after the embolism and is often associated with irregularities in the heart-beat, though in some cases the end is delayed for a few hours.

Experimentally (Rukstinat[6]) it was found that dogs with coronary air embolism died promptly, with ventricular fibrillation. If death did not immediately occur, then the air was absorbed and the dogs recovered. Death was less likely to occur if the air was prevented from reaching the brain by ligating the carotids. In other experiments F. M. Smith[7–9] found that if both main branches of the left coronary were tied, death resulted instantly from ventricular fibrillation. When only one of the main branches was tied serious results did not invariably occur, while if the right coronary was ligated about half the dogs survived for shorter or longer periods. During these experiments he took electrocardiograms and obtained the characteristic Pardee curves. Kaufmann reports absence of demonstrable change in the myocardium even seven hours after the ligature.

The *diagnosis* of the condition is obviously much the same as in coronary thrombosis, except that the syndrome is more frequent in young adults and so is not likely to be thought of. Its possibility should always be borne in mind in cases of ulcerative endocarditis and femoral thrombosis; in the latter condition it should form part of the differential diagnosis from pulmonary embolism. The presence of an irregular or slow heart action is of importance. A further stage in the diagnosis is attempting to locate the embolus. In connexion with coronary occlusion in general, Hamman,[10] in a very comprehensive essay on its symptomatology, gives the opinion that it is impossible to locate the site of the occlusion, that is, without the aid of the electrocardiograph. He points out the great variation in symptoms that follow apparently similar accidents. "To mark the extremes it is sufficient to note that the same accident may in one instance be followed, or rather accompanied, by instant death, whereas in another it may pass unnoticed and only later be accidentally discovered." Also, that since occlusion of a coronary artery may cause mural thrombi in either ventricle, one cannot say, for example, that a pulmonary embolus, coming from the right ventricle, is necessarily caused by a right coronary lesion. There is in addition the possibility of paradoxical embolism.

I should like, however, to make the following observations. The majority of coronary occlusions affect the descending interventricular branch of the left coronary artery—that is, mainly the left ventricle —and so the recognised symptomatology is that of an acute left heart failure syndrome. But if the blood pressure is not much affected and the lungs show no evidence of passive congestion, then one might reasonably deduce that the right, not the left, coronary was blocked. This would be supported by the appearance of venous congestion and also by any evidence of heart-block. In the case I have described, it was the slow and regular pulse that suggested the diagnosis, and it will be remembered that at the post-mortem there was no sign of congestion of the lungs, while in the case of Jacobi, Kenler, and Silverman, a left-sided embolism, the lungs were actually observed to deepen in red colour. In search of support for this suggestion, that main bundle block is likely to occur with right coronary lesions, I examined the electrocardiograms reproduced by F. M. Smith. Unfortunately he did not seem to have investigated the subject of main bundle block, being concerned chiefly with variations in the Q R S complex and T-wave. Also, none of the electrocardiograms were of right coronary lesions, but it is an important point that in the many left-sided lesions shown there was no evidence of main bundle block. There was only one electrocardiogram which was at all helpful; this was of a man (case 3, paper 3[9]) with a very characteristic right bundle branch block; in whom a thrombosis was found at autopsy. Which artery was affected was not specified, but the evidence favours the right. The picture showed a very prolonged P–R interval. There must be many electrocardiograms of experimental ligature of the right coronary which have not been reproduced because they were not thought to be of sufficient interest. I feel that it would in fact be of considerable interest to have this point cleared up.

There still remains the problem as to why coronary embolism is so rare relative to embolism elsewhere, in spite of the fact that the coronary blood flow is high in comparison to that of other organs. Thus it has been estimated that during exercise the minute flow is as much as 1·4 litres (Samson Wright).[11] At rest the minute volume is approximately 0·2 litre—that is, about a twentieth part of the total minute circulation volume, and yet systemic embolism is disproportionately more common. An important factor, no doubt, is that the rush of aortic blood sweeps any loose fragment well past the coronary openings which will be more or less masked by the aortic valve cusps. Also, the coronary circulation is unique in that it fills during diastole. A clot which has been dislodged probably some time during systole will have passed well out of the way by the time the coronaries commence their diastolic filling from the residue of blood in the aorta.

I wish to thank Dr. H. O. West, medical superintendent of St. Giles' Hospital, for his permission to publish the above case.

CULLEN'S SIGN
IN RUPTURED ECTOPIC GESTATION

WITH A REPORT OF TWO CASES

By IRWIN SMITH, M.D. Toronto
AND
FREDK. J. WRIGHT, B.Chir. Camb., M.R.C.P. Lond
HOUSE SURGEONS, ROYAL SOUTH HANTS AND SOUTHAMPTON HOSPITAL

IN 1919 T. S. Cullen, of Baltimore, described the occurrence of a discoloration, resembling a bruise, at the umbilicus of a patient with a ruptured ectopic gestation. The patient, a thin woman of 38, gave a history of three weeks' lower abdominal pain. There had been no menstrual abnormality. One week after the onset of the pain the umbilicus had suddenly become bluish-black, but when seen by Cullen the discoloration resembled a fading bruise. There was no umbilical hernia. Having previously read Ransohoff's description (1906) of localised jaundice of the umbilicus, in a patient with a ruptured common bile-duct, Cullen made a correct pre-operative diagnosis of a ruptured ectopic gestation.

We have recently observed two cases, each of which showed a similar discoloration in association with a ruptured ectopic gestation. In the earlier case the discoloration was at the site of an appendicectomy scar, but in the later case, which occurred whilst this paper was in preparation, the discoloration was at the umbilicus.

THE FIRST CASE

Mrs. A. B., aged 47, housewife, was admitted to hospital on Sept. 23rd, 1934, with lower abdominal pain. Twenty-three years ago—first child, normal pregnancy. Twenty years ago—three months' abortion, in bed two weeks with fever. No operation. Informed by doctor that further pregnancies were unlikely. Five years ago—appendicitis. Battle's incision, appendicectomy with drainage. No further pregnancies. General health good. Menstruation regular, 3 : 28, accompanied by slight pain in the left iliac fossa.

Four weeks before admission menstruation occurred at expected time but bleeding was unusually profuse and accompanied by severe pain in the hypogastrium and right iliac fossa. Vaginal hæmorrhage continued every day for three weeks, varying in amount and accompanied intermittently by pain. Bleeding ceased and no pain occurred for three days. The patient did not remain in bed. Five days before admission the patient "did some washing" and the pain became severe and frequent in both iliac fossæ. During the next night the patient had a sudden severe pain, and on the following morning was very surprised to notice a "bruise" in the appendicectomy scar. The presence of the "bruise" led to her consulting a doctor. No further vaginal hæmorrhage occurred. The pain was less until the day of admission, when it began to increase and also to occur in the sacral region. The "bruise" had begun as a blue discoloration. The patient is confident that there had been no injury and she had never had a spontaneous bruise before.

On examination the patient was comfortable and gave the above history clearly. Temp., 99° F.; pulse, 108; resp., 20. The cheeks were red but the lips slightly pallid. There was a discoloration on the abdomen extending from the lower third of the Battle's incision for a distance of 3 cm., beginning as a blue spot above, continued as a thin yellow line and widening to an elliptical area 5×3 cm., blue in the centre, changing to yellow at the margins. The lower third of the incision had been the site of a drainage-tube but no hernia was evident then or subsequently. After catheterisation there was still a palpable swelling to the left of the hypogastrium and general tenderness of moderate severity over the lower abdomen. On vaginal examination the swelling could be palpated bimanually. The body of the uterus was not palpable. The cervix was tender and fixed in an intermediate position. There was no blood in the vagina.

Diagnosis.—Largely on the basis of Cullen's sign a diagnosis of a ruptured ectopic gestation was made, although the exact distribution of the shades of colour was difficult to explain.

Operation.—The abdomen was opened through a lower midline incision. On opening the peritoneum there was no free fluid blood, but a considerable quantity of blood clot was found in the pelvis and surrounding an enlarged left Fallopian tube. The right tube and ovary appeared normal and no direct communication could be demonstrated between the appendicectomy scar and the pelvic viscera or blood clot. The left tube and ovary were removed and recovery was uneventful. The pathologist was unable to find definite histological evidence of a gestation but the tube had evidently been the site of an early pregnancy. The discoloration faded in two weeks. The bleeding and coagulation times, and the platelet count, determined subsequently, were normal.

THE SECOND CASE

Mrs. C. D., aged 40, housewife, was admitted to hospital on Dec. 5th, 1934, with lower abdominal pain. Four pregnancies 16, 15, 12, and 4 years ago. Last normal period nine weeks before admission. Three weeks before admission—i.e., two weeks after expected time—vaginal hæmorrhage recurred. Since then there had been intermittent vaginal hæmorrhage accompanied by an ache in the lower abdomen. For the last two weeks the patient remained in bed with general malaise and weakness and without relief of pain. She noticed that she was becoming paler. There was no urinary disturbance. On the evening before admission at 11 P.M. she had a sudden onset of lower abdominal pain, chiefly on the left side, accompanied by prostration and nausea. She vomited once. The pain resembled labour pains. There was a slight increase of vaginal hæmorrhage. The patient observed that she had suddenly become much paler. On the day of admission she felt very faint. She had a constant generalised ache in the lower abdomen associated with tenderness, but no further severe pain occurred.

On examination.—Temp., 99·6°; pulse, 136; resp., 22. There was general moderately severe pallor. The tongue was moist and clean. The lower abdomen was full but moved freely and evenly on respiration. Diffuse abdominal tenderness was present, most marked in the left lower quadrant. No tumour mass could be palpated. There was shifting dullness to percussion in the flanks. Vaginal examination revealed a fullness in the pouch of Douglas and a resistance in the left fornix. The body of the uterus was not palpable. In the ward, on careful inspection of the umbilicus, a definite faint discoloration resembling a bruise was seen, starting in the umbilicus and spreading for about 3 cm. around. This discoloration closely resembled the coloured illustration given by Cullen, but would probably not have been recognised in the ward by those ignorant of the sign. In the strong light of the operating theatre the discoloration was very definite and could scarcely have escaped notice, but care had been taken to use biniodide in spirit, instead of iodine, in preparing the skin.

Operation.—The abdomen was opened through a left lower paramedian incision. On opening the peritoneum, blood clot and abundant free blood was found. The blood did not seem to have been in direct contact with the peritoneum at the level of the umbilicus. A left-sided ruptured tubal gestation was found with a six weeks embryo in its amniotic sac. The left tube and ovary were removed. The patient was given an autotransfusion of nearly two pints of citrated blood and normal saline was poured into the abdomen. The patient did well for four days but then developed severe paralytic ileus with frequent vomiting. She responded well to gastric lavage, continuous drainage through a Ryle's tube, and to injections of acetylcholine. On the tenth day she had a temporary set-back, associated with an allergic skin eruption, but subsequent recovery was uneventful and complete. The discoloration faded in about two weeks. The patient was discharged on Dec. 29th.

REVIEW OF THE LITERATURE

This sign was apparently first recorded by Hofstätter (1909) but a correct pre-operative diagnosis was not made. It is sometimes referred to as the Hofstätter-Cullen-Hellendall sign, but it was Cullen (1919) who first presented the clinical picture. In some of the recorded cases free blood was seen shining through a thin umbilicus or through the coverings of an umbilical hernia. An example of this type was seen by one of us (I. S.) in a patient with a ruptured liver and spleen. Souligoux and Laquière (1922) recorded a similar observation, the blood in this case being seen through the coverings of a femoral hernia. A diagnosis of strangulation was made as the patient had vomited and had not passed flatus, but exploration revealed a ruptured ectopic gestation with free blood. It would, we think, be convenient to reserve the term "Cullen's sign" for the type of case where the discoloration occurs in and around the tissues of the umbilicus or of an incisional scar.

The following is a summary of reported cases as far as we have been able to discover them:—

Cullen (1918, 1919): Case described above.

Hofstätter (1909) Case 1: Lactating woman. Blue discoloration of umbilicus. Pre-operative diagnosis of strangulated umbilical hernia. Laparotomy revealed a ruptured ectopic gestation. Omentum adherent to hernia. (1922) Case 2: Ventral hernia. Permanganate colour of hernia from a ruptured ectopic gestation. (1923) Case 3: Umbilical hernia. Blue discoloration from a ruptured ectopic gestation. Cases 2 and 3 were published in 1927.

Schmid (1923) described a case that occurred in 1913. Classical signs of a ruptured ectopic gestation. A blue colour was seen shining through an umbilical hernia. Laparotomy confirmed the diagnosis.

Hanak (1920) reported a case of intestinal obstruction occurring in 1919 in a patient who in 1915 had had a right ruptured ectopic gestation associated with a blue discoloration of an incisional hernia. The patient had been operated on for a ruptured ectopic gestation on the same side within a year previously. A pre-operative diagnosis of a strangulated hernia was made, although the correct diagnosis was entertained.

Hellendall (1921). Presenting symptom was a blue-green discoloration of a small empty umbilical hernia. Appearance resembled peritoneum covering free blood. The pre-operative diagnosis was a ruptured ectopic gestation. Laparotomy showed a left unruptured tubal pregnancy with free blood in the peritoneal cavity. This observation was at first thought to have been unique.

Novak (1922) Case 1: Classical history of ruptured ectopic gestation. Around the umbilicus there was an areola of greenish-yellow discoloration. Laparotomy confirmed the diagnosis. Case 2: Classical history and signs of ruptured ectopic gestation. A greenish-blue pigmentation was present around the umbilicus. Laparotomy confirmed the diagnosis.

Jackson (1922): Ruptured ectopic gestation with free blood in the peritoneal cavity in an obese woman. Cullen's sign was visible only by illumination of the umbilicus in a dark room. The diagnosis was made before a vaginal examination or the laparotomy.

Souligoux and Laquière (1922): Details given above.

Strübe (1923): Blue coloration at the umbilicus 17 days before signs of a tubal abortion. By this time, when laparotomy showed free intraperitoneal blood, the discoloration at the umbilicus had disappeared.

Pfeiffer (1923): A blue discoloration occurred at the umbilicus seven weeks before laparotomy revealed a pelvic hæmatocele from a ruptured tubal gestation without free fluid blood.

Gold (1926): Dark blue swelling at the upper end of a midline laparotomy scar. An associated irreducible umbilical hernia contained omentum. History of an injury to the abdomen from a stick two weeks before, in addition to a typical history and signs of a ruptured ectopic gestation. Laparotomy confirmed the diagnosis.

Solowjew (1928): Observed Cullen's sign on one occasion only in over 100 cases of ruptured ectopic gestation. In his case the diagnosis was in doubt until three days after admission when a greenish discoloration appeared about the umbilicus, suprapubically and in the region of the superior anterior iliac spines. He gives an excellent coloured illustration.

Forgue (1929): Typical Cullen's sign. Ruptured ectopic gestation. Omentum adherent to umbilicus.

Lavell (1929): Cullen's sign observed twice in two successive ectopic gestations in one patient. He mentioned that the sign occurred rarely in a series of 410 cases of ruptured ectopic gestation.

Behney (1930): Cullen's sign present in only one of a series of 167 consecutive cases of ruptured ectopic gestation.

Tanner (1932) described a case where three days after the abrupt onset of severe lower abdominal pain a discoloration began at the umbilicus and spread to the lower abdomen. The bruising was attributed by a doctor to an injury, but there was no history of this. Ten days later laparotomy confirmed the diagnosis of a ruptured ectopic gestation, with free intraperitoneal blood.

Schmitz (1932): Diagnosis of ruptured ectopic gestation aided by appearance of a large blood-red colour change in and around an old appendix scar. No history of trauma. Omentum adherent to scar.

Esau (1934): A blue-coloured small umbilical hernia associated with typical skin pigmentation. Laparotomy revealed an ovarian pregnancy and adherent omentum in the umbilical hernia. Upon releasing the omentum the blue colour of the umbilicus disappeared but the pigmentary changes in the skin persisted.

Stabler (1934): Presenting symptom was a discoloration of the abdominal wall, consisting of a very dark mark one inch below the umbilicus, a separate "bruise" between the umbilicus and pubis, and a third area in the inguinal fold. The correct pre-operative diagnosis was made. Free blood was present in the peritoneal cavity from a left unruptured tubal gestation.

DISCUSSION

The occurrence of Cullen's sign in association with intraperitoneal hæmorrhage is clearly not fortuitous, but its explanation is obscure. Many theories have been propounded to explain the phenomenon. Hofstätter suggests that the colour change in a hernia a few hours after rupture of the gestation is due to free blood seen shining through the thinned-out abdominal wall. This observation is substantiated by Souligoux and Laquière (1922), Schmid (1923), and Hellendall (1921). Where a physiological or pathological weakening of the abdominal wall is present, especially when associated with adherent omentum or bowel, blood may track to this point and become trapped, thus giving rise to the discoloration. Esau (1934), among others, supplies corroborative evidence. Hofstätter considers the possible rôle played by lymphatic channels in the transportation of blood or its derivatives to the umbilicus, especially where the omentum is adherent to the abdominal wall. Strübe (1923) is of the opinion that in some cases dilatation and congestion of the umbilical veins from anastomosis with those of the broad ligament may explain the occurrence of Cullen's sign. Forgue (1929) favours the tracking of blood along omental adhesions as the likely cause. In view of its infrequent occurrence, Stabler (1934) suggests that an abnormal break of continuity of the peritoneum may be a necessary factor.

The lymphatic mode of development is, however, usually the most probable explanation. On this hypothesis the appearance of Cullen's sign may be compared with the occurrence of nodules of carcinoma spreading to the umbilicus from peritoneal carcinomatosis. The changing shades of colour might be explained as due to oxidation of absorbed blood pigments travelling in lymphatics connecting the umbilicus with the peritoneal cavity or in abnormal lymphatic channels at the site of previous incisions.

Cullen's sign is peculiarly rare. Hofstätter saw only three cases between 1909 and 1927. Stein (1925) in a series of 106 cases and Jonas (1933) in a series of 90 did not have a single example. Its rarity has been mentioned by Behney (1930) and Lavell (1929) (see above). There is usually a history of over two weeks' lower abdominal pain and sometimes of an acute exacerbation of the pain, followed by the sudden appearance of the discoloration which fades slowly. Although this is a common history in any case of ruptured ectopic gestation, it perhaps suggests that repeated small intraperitoneal hæmorrhages, rather than a single severe hæmorrhage, favour the appearance of Cullen's sign.

A blue discoloration of the umbilicus is not, however, pathognomonic of intraperitoneal hæmorrhage. zum Busch (1922) records an example caused by a hæmorrhage into an adherent ovarian cyst and Gold (1926) an example in the skin over an umbilical hernia containing strangulated omentum. Hellendall (1934) records an example in a case of doubtful origin, but possibly associated with cirrhosis of the liver and portal obstruction. None of these cases simulated a ruptured ectopic gestation, but Schumann (1923) recorded a case where, on the basis of a typical Cullen's sign, he erroneously made a diagnosis of a ruptured ectopic gestation. Laparotomy revealed a two months' intra-uterine pregnancy and bilateral acute salpingitis. Pus was oozing from very congested tubes, but there was no free intraperitoneal blood. No explanation was found for the typical umbilical ecchymosis.

Cullen's sign has also been recorded in cases of hæmoperitoneum not due to a ruptured ectopic gestation by Sternberg (1922) and Kapsinow (1925). Sternberg (1922) described a case where a hæmorrhagic ascites due to an adenocarcinoma of the liver was associated with a blue discoloration of the umbilicus. Kapsinow (1926) recorded the case of a child in whom a hæmorrhagic ascites, due to deposits in the peritoneal cavity, secondary to sarcoma of the kidney, was associated with a blue discoloration of the umbilicus. Stutzer observed a brown-blue discoloration of the abdominal wall about the umbilicus and in the right lower abdominal quadrant, three days after the onset of an acute hæmorrhagic pancreatitis. Petrivalsky (1931) records similar findings in three cases of acute hæmorrhagic pancreatitis.

We conclude, therefore, that Cullen's sign is a rare indication of intraperitoneal hæmorrhage; that it is not without fallacies, but that it may occasionally be an aid to diagnosis and sometimes even the presenting symptom.

We are indebted to Mr. H. J. Nightingale and to Mr. S. B. Chambers, honorary surgeons to the hospital, for permission to publish the above cases.

Clinical and Laboratory Notes

PREVENTIVE IMMUNISATION OF SCARLET FEVER

BY J. LITT, M.B. Edin.

ASSISTANT MEDICAL OFFICER OF HEALTH AND ASSISTANT SCHOOL MEDICAL OFFICER FOR BOLTON

DURING the year 1933 there was a sharp epidemic of scarlet fever among the Bolton school-children which was specially noticeable from about May to December, the peak period being the month of October of that year. For the most part the fever was of the mild type, but in three elementary schools the number of cases was increasing, and it was decided to offer the parents protection for the children attending them.

The protection took the form of three fortnightly intramuscular injections of scarlet fever prophylactic toxin (Burroughs Wellcome and Co). The initial dose chosen was 500 skin test doses, the second 5000, and the third 20,000. The accompanying Table, which has been corrected to December, 1934, shows the number of children in each department of the three schools who were immunised. Since the completion of immunisation in each school. 150 cases of scarlet fever have been notified among the non-immunised group. The majority of the cases were treated in hospital and the diagnosis confirmed. One only has been notified among the completely immunised group. The remaining four cases which occurred among the immunised group received one or two injections only, and therefore were not completely immunised.

1 School.	2 Date of third inoculation in 1933.	3 Dept.	4 Children immunised.	5 Cases of Sc. F. in immunised up to Dec., 1934.	6 Children not immunised.	7 Cases of Sc. F. in children not immunised.
A.	June 29	Infant.	50	1*	140	8
		Sen. & M.	68	—	208	12
B.	Sept. 27	Infant.	27	—	198	34
		Sen. & M.	50	—	155	11
C.	Nov. 23	Infant.	117	1†	309	51
		Sen. & M.	226	2* 1‡	498	34
Total	..	..	538	5	1508	150

Sen. & M. = Senior and Mixed; * Had two injections only; † Had one injection only; ‡ Received three injections.

The four children in column 5 who had scarlet fever after one or two injections are excluded from the total in column 4 and included in the total in column 6.

There were very few reactions after the initial and final injections. Reactions were noted more after the intermediate dose of 5000 skin test doses, but these were for the most part slight. The Dick test was not carried out.

I am indebted to Dr. R. M. Galloway, medical officer of health for Bolton, for his permission to publish this note.

A CASE OF TUBERCULOUS MENINGITIS WITH RECOVERY

By F. G. Hobson, D.S.O., D.M. Oxon., F.R.C.P. Lond.

HONORARY PHYSICIAN, RADCLIFFE INFIRMARY AND COUNTY HOSPITAL, OXFORD

Recovery from a proven tuberculous meningitis is so rare as to merit record.

A man, aged 24, was admitted to the Radcliffe Infirmary, from Dr. Tighe, of Eynsham, on July 11th. 1934. He was a solderer at the Pressed Steel Works, Cowley. Family history: Nil ad rem. Past history: Childish ailments only. Radical cure of hernia 1933.

Present illness.—For six weeks before admission he had experienced general joint pains, which had affected various joints, but mainly the right ankle and knee, and these had caused considerable loss of sleep. For two weeks he had noticed gradually increasing stiffness in his neck and shoulders, and steadily mounting headache, with deafness and tinnitus in the left ear. For one week he had been feeling seriously ill, had been constipated and vomiting at irregular intervals.

Condition on admission (July 11th).—Pulse-rate, 68; respiration, 20; temp., 99·2° F. Alert, good witness; looks ill. Tongue furred; colon loaded with scybala; heart and lungs normal. Marked neck rigidity without opisthotonus. Pupils react normally to light and accommodation. Discs normal. Slight nystagmoid movements of eyes to the right. Definite impairment of hearing in left ear. Cold calorie test also showed marked reduction in time and amplitude; no detailed measurements made. Tendon reflexes all normal and abdominal reflexes present. Kernig's sign present. Plantar response: right, flexor; left, *indefinite. On the following day the plantar was* definitely extensor. The following were the findings in the cerebro-spinal fluid:—

Date in 1934.	Organisms.	Globulin.	Cells.	Chlorides.
July 11	1 *B. tuberc.*	+ + +	Poly. Endos. Lymph.	620
,, 13	+ T.B.	+ + +	—	550
,, 26	0	—	Lymph. Endos.	620
,, 30	+ T.B.	—	Poly. Lymph.	630
Aug. 12	0	+ + +	—	680
,, 14	0	—	—	—
,, 31	0	+ + +	Poly.	690
1935. March 20	0	Trace.	None.	800

Radiography of the skull and sinuses revealed no abnormality.

Progress of illness.—During July and August he continued to be gravely ill, suffering from severe headaches at frequent intervals, relieved by lumbar puncture and morphia and recurrent vomiting, worse in the morning. His morale was excellent, in spite of his suffering, and his mind remained clear while his physical condition steadily deteriorated.

Sept. 12th: general condition very poor; emaciation extreme, but still bright and intelligent: still suffering from intermittent headaches and vomiting daily. Neck rigidity less marked. Slight weakness of L. VII. Marked impairment of hearing L. VIII. Left plantar response extensor. These signs suggest a tuberculoma in the posterior fossa involving the L. VII, VIII nerves and associated with a tuberculous meningitis. He was moved on to the balcony, and from this time on began to improve, his headaches diminished, he rarely vomited, and his appetite improved. The progress of his weight was:—

Sept. 28th, 1934	6 st. 13 lb.
Oct. 7th, ,,	7 st. 6½ lb.
,, 12th, ,,	7 st. 11 lb.
March 12th, 1935	9 st.

On Oct. 5th Mr. R. G. Macbeth examined the ears and reported as follows:—

	Right ear.	Left ear.
Watch	3 in.	¼ in.
Swabach	4 secs.	2 secs.
Cold calorie test	45 secs.	67 secs. before onset.

Membranæ tympani normal.

On Oct. 17th the general condition was much improved; there was occasional slight headache; no abnormality was detected in the central nervous system other than impaired hearing in the left ear. On the 20th he was discharged from hospital and sent to convalesce at the seaside. On March 6th, 1935, he was readmitted for investigation and re-examination. Feels and looks well; weight, 9 st.: complaining of a tendency to perspire at night and slight cough; general physical examination negative. Report on ears (Mr. Macbeth):—

	Right ear.	Left ear.
Watch	6 in.	12 in.
Rinné test	+	+
Swabach	5 secs.	3 secs.
Cold calorie test	40	60

No nystagmus. Membranæ tympani normal.

The temperature was normal: no T.B. were found in one specimen of sputum. Radiography of sputum showed one small healed focus at the *hilum of the left* lung: in the abdomen there was no evidence of any tuberculous or calcified glands. The Wassermann reaction was negative in the blood and cerebro-spinal fluid.

It seems probable that the general symptoms which preceded the meningitic manifestations represent a tuberculous bacillæmia, with a lodgment and the development of tuberculoma in the posterior fossa in relation to the L. VIII (and VII.) nerves. In this instance there was a pure tuberculous meningitis possibly confined to the posterior fossa and the meningitis was not the expression, as it usually is, of a general miliary tuberculosis. The improvement in the general condition and the partial recovery of the L. VIII nerve all point to the fact that the infection has been overcome and the local lesion is healed or healing.

FEMORAL HERNIA ASSOCIATED WITH PARTIALLY DESCENDED TESTIS

By James Cook, F.R.C.S. Edin., D.P.H.
DEPUTY MEDICAL SUPERINTENDENT, BIRKENHEAD MUNICIPAL HOSPITAL

The following case illustrates the rather unusual association of partially descended testicle with a femoral hernia.

A well-developed labourer, aged 23, was admitted to Birkenhead Municipal Hospital on Jan. 6th, 1935. He stated that a lump appeared in his right groin twelve months previously, and that he had never been able to reduce it. Thirty hours before admission he was seized with acute abdominal pain, and since then had vomited thrice. His bowels opened well on the day of admission, and there was no abdominal distension.

Examination showed the absence of the right testis from the scrotum, and the index-finger could not be passed into the right inguinal canal. A swelling about the size and shape of a normal testis was found occupying the right femoral canal. It was irreducible and gave no impulse on coughing. The mental condition of the patient was such that little reliance could be placed on his history of the duration of the condition, or of the absence of testicular sensation, so that it seemed possible that we were dealing with a femoral type of ectopic testis. The femoral canal was exposed by the inguinal route, and an ordinary femoral hernia was found containing a knuckle of small intestine. The intestine was viable, and the Lotheisen operation was completed. In the inguinal canal an extremely atrophic testis was found with an associated hernial sac. The testis was removed since it appeared to be little more than fibrous tissue. The inguinal sac was dealt with and the operation completed in the usual manner.

I have to thank Mr. R. A. Grant for permission to publish this case.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF PSYCHIATRY

At a meeting of this section held on April 9th the chair was taken by Dr. David Forsyth, the president, and Dr. J. R. Rees opened a discussion on the Problems of

Out-patient Clinics for Psychoneurotics

He asked his audience to set in order the various localities in which they would advise a poor, obsessional patient to live if he wanted to find provision for treatment. Much more information was needed about the activities of clinics throughout the country; often information was obtained by accident. There was urgent need for treatment; R. D. Gillespie had estimated that one person in thirteen in these islands needed psychological treatment, and few would quarrel with this estimate. There were 162 clinics or early treatment centres in the British Isles, but most of them provided only a diagnostic service, and less than half could provide adequate treatment, including persuasion, re-education, suggestion, or mental analysis. Probably not more than thirty treatment clinics were available for the poor. There was little to be said in favour of associating the clinic with the mental hospital, which still scared people, but there was much to be said for making it a part of a general hospital. It was not, however, helped by the bustling medical atmosphere of a hospital. Perhaps the ideal location was a special building attached to the general hospital, so that close liaison could be maintained while the psychotherapeutic work was able to provide for its special needs of more medical time, more quiet, less nursing, and more sociological approach. Much was to be gained by seeing children and adults in the same clinic. The only real early treatment of mental disorder was the treatment of childhood difficulties.

Some 46 per cent. of the cases coming to such a clinic suffered from anxiety neuroses; 13 per cent. from conversion hysteria; 11 per cent. from obsessive-compulsive neuroses; and 2 per cent. from neurasthenia. It must be clear that the clinic did not deal with the mental defective. No more than 5 per cent. would be referred to mental hospitals. In many of the clinics established under the Mental Treatment Act, 1930, this figure rose as high as 22 per cent. This suggested that psychoneurotics were not so often referred to these clinics which were associated with mental hospitals and staffed by their officers. Since the psychoneurotic problem was so great, attention of local authorities should be directed to the need. The services of the clinic should be available for the courts, and the provision of beds would undoubtedly increase its efficiency. Each clinic must acquire a body of information about services of all kinds available to patients. The staff should include physicians with adequate training in psychopathology and psychotherapy. The primary aim must be therapeutic. The points of view of the mental hospital and the psychopathologist must be coördinated to the service of the clinic. Work might, for the time being, be concentrated on the more intelligent type of patient; for the others, the methods of the general hospital were likely to be successful. There was no age limit; a child of a few months could be helped through its parents, and benefit had been obtained in patients of seventy and over. The standards of treatment should be in every way comparable with those of private practice, every bit as careful and accurate and unhurried. The educational value of the clinics was fully as important as in any other branch of medicine; the uncured—or cured—neurotic patient produced a greater effect on society than the corresponding surgical patient. The out-patient problem of the future would demand a great increase in the number of trained and carefully picked psychiatrists. Mildly pathological motives were responsible for most people's interest in psychology. The cost of private treatment would always be a difficulty, and the State would have to concern itself with much of the treatment. Group treatment by suggestion was possible and time-saving. For the difficult child, the team method seemed to be the best that could be devised. The social service of the clinic was useful for adults as well as children. The shortage of trained medical psychotherapists might make it necessary to recognise a body of lay workers similar to the Chartered Society of Trained Masseuses.

Dr. E. Mapother said that the Maudsley Hospital was much more a diagnostic centre than was the Institute of Medical Psychology. Most clinics were not and could not be confined to psychoneurotics.

Incipient organic and psychotic cases were inevitably treated. In some localities the mental hospital might well prove to be the best place for the clinic; unfortunately, the psychoneurotic in the general hospital tended to drift to the neurological rather than the psychiatric department. The hysterical reaction was common among those of rather low intelligence, and anxiety was found in all grades. The appointment system was most desirable so far as it could be arranged, but was very difficult in a large diagnostic clinic.

Dr. JOHN RICKMAN said that psycho-analytic clinics could not cope with the thousands of people needing help; the turnover did not amount to much more than thirty a year. The interest of their work lay in its relation to research. The psycho-analytic clinic might not treat many people, but it trained a large number of workers, and the training was exceedingly long and arduous. Turkey and Russia, when facing a great problem of education, had found that the first task was to get a body of teachers. The first problem of psychotherapy was to provide a great number of competent workers; the rest would follow. Freud had once said that the best method of reducing the time of an analysis was to do it properly; he would probably say that the answer to the problem of the psychoneuroses was the adequate training of psychotherapists.

Mrs. DOROTHY HARDCASTLE spoke for Dr. R. D. Gillespie, who was not able to be present. He agreed that clinics must not be run for psychoneurotics alone, and that training could not be divorced from the mental hospital. There was great need for a critical attitude towards results and for control groups treated by various methods. A great disadvantage of the clinic in the general hospital was the heavy case-load and prevention of selection; coördination was, however, favoured, and this was very important. Psychiatry should be an integral part of general medicine.

Sir ROBERT ARMSTRONG-JONES recalled the foundation of the out-patient clinic at St. Bartholomew's Hospital, and the opposition it had encountered. The line between psychosis and psychoneurosis was not easy to draw, but was important. The West Riding Mental Hospital had had an out-patient department in Crichton Browne's time, with Hughlings Jackson and Ferrier on the staff.

Dr. RALPH NOBLE said that correct diagnosis, in the first place, was essential, and involved very thorough investigation. In his experience a quiet atmosphere could be found in a general hospital if sought. The use of sedatives should not be entirely neglected—even if the patient was laying bare his soul. The clinic should be separate from the general hospital, but very closely allied to it. Amidst the great number of patients needing help, it was not possible to allot a thousand hours to every patient. Psycho-analysis, apart from research, was impracticable. He liked to give a whole day to a new case, working out the important factors, and giving the patient something good to go home with so that he came again. The psychotherapist must be a psychiatrist. One of the best trainings was a period of general practice. A physical examination was of the greatest importance.

Dr. W. C. SCOTT described out-patient therapeutic work at the Maudsley Hospital of 3673 patients: 32 per cent. suffered from neuroses, 36 per cent. from functional psychoses, and 11 per cent. from neurasthenia. Many had serious psychoses. Different types of service were needed for these different types of patient, and therefore a general psychiatric service should be available. The average time per visit had been eleven minutes, ranging from two minutes to an hour and a half. The ideal seemed to be to have the clinic associated with a psychiatric hospital. Psychiatric problems were related to the whole problem of public health. Adult and child clinics should feed each other. Neuroses were found in all grades of intelligence; high I.Q. was not so necessary, even for psycho-analysis, as had been thought. The most pressing need for the future was the development of psychiatric hospitals.

Dr. DORIS ODLUM found that her figures from Bournemouth and Hove corresponded very closely with those of Dr. Rees. Bed facilities were most essential; of 1000 cases, 10·6 per cent. of the Bournemouth and 8·6 per cent. of the Hove cases had been admitted for rest or change of environment. Of the first group, 83·7 per cent., and of the second group, 67·5 per cent. had recovered or were much improved. These patients could not have achieved good results as out-patients. "Daily out-patients" was an institution that helped many who could not be admitted, or did not need to be. The patients spent their whole day living in the hospital under its routine. The arrangement had proved most valuable and might well be extended.

Dr. LOUIS MINSKI said that the North London clinics, opened as departments of the Maudsley Hospital, had begun as diagnostic clinics, but had had to become therapeutic. Many of the patients were of low intelligence, but had responded well to psychotherapy. Quite long interviews were given, supplemented by special appointments at the Maudsley. A skilled and highly trained social worker was essential.

Dr. NEUSTATTER discussed methods of treatment. Often "first aid" could be given, but for real analytic work three-quarters of an hour three times a week was desirable. A thorough understanding of the case did not necessarily enable the physician to do anything about it. It was a great pity to separate psychiatry and psychotherapy. The psychotherapist who never saw psychiatric patients was apt to get out of touch from the diagnostic angle.

Dr. D. N. HARDCASTLE described the initiation of an out-patient and child guidance clinic at the Herts Mental Hospital. The object of locating it there had been to abolish the stigma of the asylum. The clinic was housed in the mental hospital but run by a staff from London, and this fact broke down the patient's prejudice. If beds were needed the patients entered as voluntary boarders. A similar clinic might well be run in every mental hospital.

Dr. T. E. A. STOWELL regarded "prophylactic treatment" as a contradiction in terms. The best prophylactic for mental disorder was administered by the boot of the older boy at the public school. The sickness due to psychical disorders was a tremendous charge on capital, and employers would readily support clinics if a cast-iron case could be presented to them.

Dr. LETITIA FAIRFIELD said that the Maudsley clinics were very extensively used by the public assistance department of the L.C.C., and were regarded as of the greatest possible value. Patients who had been on the public funds for a very long time were returned to work after treatment. The clinics were also very valuable educationally in assisting adjustment to work and preventing the genesis of the young criminal. The value of the in-patient bed and of multiple methods of disposal of the patient could not be exaggerated. The psychotherapeutic clinic would be of the less value the more it was left isolated.

Dr. CLIFFORD ALLEN suggested that neurologists were not yet fully educated in psychotherapy, but believed that neuroses were due to constitution and constipation, and could be cured by bed and bromide.

Dr. STACEY WILSON emphasised the effect of the colon on the mind. If the colon were tender in a mental case benefit would be obtained from intestinal antisepsis and antispasmodics.

Dr. A. E. CARVER described an experiment that failed: the Nerve Hospital at Birmingham. Its initiation had provoked great opposition among the medical profession. It had had to compromise, and cease to be a psychotherapeutic hospital. The first step was to convert the doctors.

Dr. REES replied.

ROYAL SANITARY INSTITUTE

AT a sessional meeting held in London on April 9th to consider the problem of

Maternal Mortality

Mr. EARDLEY HOLLAND dealt with factors of special interest in maintaining the present rate of mortality. One of these was an unfavourable change in the methods of obstetric practice. In the last 15 to 20 years there had been a remarkable widening of the indications for intervention during labour, in spite of the efforts to frustrate it on the part of leading teachers and text-books. In speculating on the factors which had led to this he suggested that the following had been chiefly responsible: (*a*) The increasing employment of analgesics and anæsthetics which have by now become almost universal; in a certain proportion of cases these slow down labour and lengthen it, weaken the natural forces, and so lead to an increase in the forceps-rate. (*b*) The hundreds of little hospitals giving local practitioners the opportunity of performing Cæsarean sections and other obstetric operations. The number of Cæsarean sections had increased in an astonishing manner. In the (final) Newman report 160 sections were reported in the second series of 3805 deaths investigated; many of these had been done after previous attempts at forceps delivery. "There may be a tendency," the report suggested, "to resort to Cæsarean section as treatment of complications of labour, perhaps without due consideration of other methods of obstetrical treatment." Whitridge Williams, in the fifth edition (1923) of his text-book, explained the rising mortality of childbirth on the supposition "that many practitioners in urban areas have been led astray by the teachings of those who regard labour as a pathological rather than a physiological process, with the result that interference upon insufficient indications is frequently undertaken by those who do not fully appreciate the risk involved"; inquiry by the Massachusetts State Medical Society showed that in 1921 after puerperal infection Cæsarean section was the most frequent cause of death. (*c*) Uninstructed antenatal work with its mistaken notions about "disproportion," "post-maturity," the "unengaged head," and the resort in consequence to unnecessary interference. (*d*) Any sort of interference with the course of normal pregnancy and labour, by meeting the demand of the patients for shorter labours, or by extension of the indications for drug or operative induction to suit the convenience of the patient, her friends, the doctor, the nurse. (*e*) An exaggerated idea of the value of the infant's life as compared with the life or health of the mother—due to the fact that nowadays pregnancies were spaced, regulated, and relatively rare. This interesting social change in reproductive method was exerting a great influence on obstetrical procedure. Among adverse factors due to changing habits and social circumstances were (1) a relative increase in primiparity, with restriction in the size of the family; (2) the increasing average age of all mothers, primiparæ and multiparæ.

The problem of lowering the mortality had two distinct aspects. One was presented by the so-called "black" areas. Rochdale was for many years in the unenviable position of having one of the highest rates in England. During the three years 1929–1931 it was 10· per 1000. Study of the circumstances made it appear likely that a large proportion of the deaths had been due to too frequent intervention. The support of the medical profession and of the midwives was enlisted, and the interest of the community in general, and of the women in particular, awakened through the pulpit, the platform, and the press to the medical facts. The women thus were taught to make use of the antenatal clinics, to report at the first sign of any abnormality, and to refrain from attempting to persuade the doctor or the midwife to hurry the course of labour. The "drive" was begun in 1931. For the three years 1932–34 the maternal mortality of Rochdale had fallen from 10 per 1000 to 3·9, or about the same rate as the rest of the country. There was no alteration in personnel; merely a change of spirit and of method. In the hospital it was particularly noticed that women with complications of labour were being sent in increasing numbers at a stage when the complication was capable of being treated with greater safety. To reduce the mortality in the black areas should be easy; but further to reduce the mortality to a figure below the existing best would take much time, and the country must be asked to wait patiently until the standard of practice had been remarkably raised and midwifery was undertaken by a select corps of men and women, based on high-class obstetric institutions. The central and local authorities of this country had made a great mistake in believing that the creation of an efficient obstetric service was merely an administrative problem.

THE SITUATION IN MANCHESTER

Dr. R. VEITCH CLARK (M.O.H. for Manchester) asked for consideration of a few facts which had come to light in the practice of the maternity service of Manchester. The figures for puerperal sepsis showed a definite fall in the last four years from 1·7 to 1·0 per 1000 births. The rate for non-septic maternal deaths, which was 2·8 for the quinquennium 1926 to 1930, fell to 2·0 in 1932, and then rose remarkably in 1933 and 1934 to 3·4. During the past four years there had been on the average just over 6000 women seen at the clinics in the city, excluding those held at the voluntary hospitals, each woman making 4–5 attendances. The total number of births in round figures was 12,000, so that over 50 per cent. of the pregnant women were being seen antenatally by the public medical service. In the seven years previous the annual number of antenatal attendances varied from 1400–8000. The fall in sepsis might, he thought, be definitely associated with this fourfold increased antenatal service. Conditions calling for interference were regarded as one of the prime sources of puerperal sepsis, and these could be recognised to a considerable extent by antenatal care. But what about the non-septic puerperal deaths? In the years 1926–29 the average number of deaths from eclampsia was 7; in 1930–33 the average was 3·4—rather less than half. Antepartum hæmorrhage gave an average of 6·5 deaths per annum in 1926–29, an average of 2 in 1932–33. The lowered incidence of these two complications continued up to the present year. Eclampsia was recognisedly a toxæmic death, and half at least of the serious cases of antepartum hæmorrhage were probably toxæmic in origin. In the period 1933–34 placenta prævia caused 5 deaths in 1933 and 9 deaths in 1934, as against 1·7 for the three preceding years. The figures, although not large, did suggest that antenatal work had contributed to a fall in puerperal sepsis and in the recognised toxæmias of pregnancy.

Dr. Veitch Clark had analysed the source of professional attendance on childbirth in Manchester for the years 1930–33 (see Table). In 1933 out of 12,633 births, 4362 were attended by midwives, 971 by doctors, and 6088 went to hospitals and nursing-homes. The balance of 1,212 cases were attended in their own homes by the extern practice of St. Mary's Hospital. Over 10,000 received attention either from midwives or in hospital. Of the 110 midwives in the city practising midwifery only 50 were dependent solely on midwifery for their living, and 18 of these lived with relations. Of the 60 others, all married women, 45 were definitely not in full-time practice, and 15 also carried on domestic duties. No woman, he said, could maintain her manual skill and sustain her knowledge unless fully occupied in the practice of her profession and assured of a reasonable competency. He would prefer a scheme whereby the midwives were part of the extern connexion with a hospital with an income guaranteed by the local authority. Only 900 cases per annum out of the 12,000 were attended by doctors in their private capacity, with additional 2413 cases on the formal request of midwives. There were 650 practitioners in active work in Manchester, and obviously experience in obstetrics was not available in sufficient amount to maintain skilled practice. That being so he saw no practical solution of the difficulty in a revision of the medical curriculum, but rather in the development of post-graduate work. But while expert work was essential the enlightened coöperation of the mothers should be secured by direct personal contact in antenatal and postnatal clinics.

City of Manchester: Births Attended by Doctors and Midwives

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 6TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2256; diphtheria, 1264; enteric fever, 28; acute pneumonia (primary or influenzal), 1486; puerperal fever, 45; puerperal pyrexia, 112; cerebrospinal fever, 36; acute poliomyelitis, 1; encephalitis lethargica, 12; continued fever, 1 (Battersea); dysentery, 20; ophthalmia neonatorum, 75. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 13th, was 3737, which included: Scarlet fever, 1122; diphtheria, 1602; measles, 22; whooping-cough, 347; puerperal fever, 23 mothers (plus 8 babies); encephalitis lethargica, 270; poliomyelitis, 2. At St. Margaret's Hospital there were 17 babies (plus 10 mothers) with *ophthalmia neonatorum.*

Deaths.—In 121 great towns, including London, there was no death from small-pox or enteric fever, 29 (0) from measles, 8 (1) from scarlet fever, 24 (4) from whooping-cough, 45 (7) from diphtheria, 37 (12) from *diarrhœa and enteritis* under two years, and 184 (33) from influenza. The figures in parentheses are those for London itself.

The number of influenzal deaths remains almost stationary, the reported deaths for the last few weeks (working backwards) being 184, 181, 175, 145, 139, 83, 91, 83, 91, 71, 56. This week these deaths were reported from 59 great towns, Manchester reporting 15, Birmingham 10, Portsmouth, Sunderland, and Stoke-on-Trent each 7, Blackburn, Smethwick, and Swansea each 6, Croydon and Liverpool each 5. (During the same week Glasgow reported 11 deaths, as against 33 in the previous week.) Wigan, Birmingham, and Wolverhampton each reported 3 fatal cases of measles. Three deaths from diphtheria occurred at Bournemouth and at Sheffield.

The number of stillbirths notified during the week was 275 (corresponding to a rate of 44 per 1000 total births), including 44 in London.

REPORTS AND ANALYSES

SEAGER'S EGG FLIP

(SEAGER, EVANS AND CO., LTD., MILLBANK DISTILLERY, DEPTFORD BRIDGE, LONDON, S.E.8)

THIS preparation is a thickish yellow permanent emulsion tasting pleasantly of egg and sweetened wine. When analysed, the following results were obtained:—

Alcohol	20·0 per cent. (by volume).
Total solids	14·0 ,, ,,
consisting of—	
Carbohydrates	8·0 ,, ,,
Proteins	1·71 ,, ,,
Fat	3·26 ,, ,,
Mineral matter	0·4 ,, ,,

Preservatives were tested for with negative results. The analytical figures are consistent with a 10 per cent. emulsion of egg-yolk in a sweetened wine of 20 per cent. alcohol content.

This "flip" is a convenient and agreeable form of taking eggs. In addition it is an obvious food tonic which is available for consumption at a moment's notice, and therefore particularly suited for use in the sick-room.

SCARBOROUGH HOSPITAL.—It was stated at the annual meeting that £300 was lost last year through road accidents. The Mayor pointed out that it was no credit to the motoring public as a whole that they did not respond more freely towards the cost of these accidents. The new hospital is being built, but there has been some delay in its progress because of the underground water at the foundations. A further £8000 has been added to the funds but £20,000 is still required. The new hospital will cost about £5000 more to run than the old, and the board has decided to adopt a contributory scheme.

REVIEWS AND NOTICES OF BOOKS

Human Sex Anatomy

By ROBERT LATOU DICKINSON, M.D., F.A.C.S. London: Baillière, Tindall and Cox. 1934. Pp. 145. 45*s.*

"It appears well within bounds to affirm," says the author in a foreword, "that many of our present beliefs concerning average sex experience and normal sex life have the status of surmises standing on foundations no more secure than general impressions and scattered personal histories."

That Dr. Dickinson has devoted much of his life to establishing on proper foundations our knowledge of reproductive processes is known to all who have read his previous books. The same end is pursued with undiminished vigour in this volume which is produced, under the auspices of the National Committee on Maternal Health, in a series entitled Medical Aspects of Human Fertility. Dr. Dickinson has brought to bear upon this work an enormous clinical experience. He is gifted with outstanding artistic ability, and the chief feature of this book is the collection of beautifully executed drawings which occupy the last 120 pages of the book. This is divided into two essential parts of approximately equal length. The first, consisting of text and commentary, includes nine chapters on purpose and methods; the bony pelvis; uterus, ovaries, and tubes; the vagina; the vulva and breast; male genital anatomy; the anatomy of coitus; the anatomy of the control of conception; conclusion and programme. To these chapters is appended an extensive bibliography. The second part of the work consists of illustrations assembled under headings which correspond to the chapters in Part 1.

The considerable cost of the book is entirely justified by its format, upon which the publishers deserve congratulation. The illustrations cover a field of anatomy hitherto little explored and fill an important gap in our previous knowledge. Some of them have already appeared in books earlier produced by the Committee on Maternal Health, and have already proved useful. The chief criticism applicable to this volume relates to the author's literary style. This is a source of distress to many readers who have found good cause to regret that Dr. Dickinson does not take as much trouble about the composition of his sentences as he does about the drawing of his pictures.

The book will be especially valuable to specialists in gynæcology and genito-urinary diseases.

L'infarctus du myocarde

By EDUARDO COELHO, Professeur à la Faculté de Médecine, Médecin de l'Hôpital de Santa Marta Lisbon. Paris: Masson et Cie. 1934. Pp. 212. Fr.35.

As far as pathological anatomy is concerned little has been added to our knowledge of infarction of the myocardium since it was first described at the end of the 19th century, though a mass of communications on this aspect of the disease have been published. The clinical picture and symptoms have received less attention, and this accurate clinical and electrocardiographic study is welcome. Prof. Coelho begins in the orthodox fashion with a well-illustrated description of the coronary circulation. Then follows a chapter relating the personal experiences of the author in experimental occlusion of the coronary arteries in dogs. A detailed description is given of the immediate and the remote results of occlusion and their bearing on human pathology is discussed. The rest of the book is devoted to clinical observations on a large series of cases. Dr. Coelho is convinced that this condition is much more common than has yet been realised, and believes that it is nearly always possible to diagnose it. The most important aid to diagnosis is undoubtedly the electrocardiograph. A physician familiar with the clinical picture, who has been able to get an adequate history and an electrocardiogram, should make no error in the diagnosis between myocardial infarction and an acute abdominal condition or a cardiovascular neurosis. As for prognosis, the author is inclined to think that this is not so grave as is thought, and that in most cases recovery may be expected. He admits that it is difficult to prophesy the outcome in an individual case. When death occurs it is nearly always the result of ventricular fibrillation. This is an interesting and informative monograph, which contains an extensive bibliography.

Handbook of Anæsthetics

Fourth edition. By J. STUART ROSS, M.B., Ch.B., F.R.C.S.E., late Lecturer in Practical Anæsthetics, University of Edinburgh; and H. P. FAIRLIE, M.D., Anæsthetist to the Western Infirmary, the Royal Hospital for Sick Children, and the Dental Hospital, Glasgow. Edinburgh: E. and S. Livingstone. 1935. Pp. 299. 10*s.* 6*d.*

THIS edition of Ross's well-known book is the product of Dr. Fairlie alone, and it has lost nothing in the new control. Dr. Fairlie has wisely continued to make no change in the general scheme and arrangement, but has brought the matter up to date. It continues to be, as it has been since its first appearance, one of the best guides for the student or practitioner who is practising anæsthetics. It is not a book for the specialist. Particularly good is the instruction in the use of ether. Nitrous oxide and oxygen is not so well or so carefully handled, no doubt because its use in major surgery is more for the specialist than for the occasional anæsthetist. The brief discussion of the physiology of anæsthesia and of shock is well done, and tells all that it is essential for the student to bear in mind. The print and production of the book are excellent, and we have no doubt of its continued success as a text-book for students.

Textbook of Biology

By E. R. SPRATT, D.Sc., F.L.S., F.I.H., A.K.C., formerly Lecturer in Botany, King's College, London; Head of the Biological Department, Norwood Technical Institute; and A. V. SPRATT, M.Sc., F.I.H., A.K.C., Head of the Science Department, King's Warren School, Plumstead. London: University Tutorial Press Ltd. 1935. Pp. 646. 9*s.* 6*d.*

AS an aid to practical work this book will be found of distinct value, since the descriptions are clear and the diagrams are excellent. The facts described, however, are given little significance in relation to general biological principles. Important subjects such as sex, reproduction, development and growth are hardly mentioned in their dynamic aspects, and the one general chapter on heredity and evolution is inadequate and in many respects misleading. No idea is given of the problems which biologists are at the moment attempting to solve. Since most students taking elementary biology will never study the subject more fully, it is essential that they should be made aware of these broader aspects of the subject which are of importance to every educated man—the view obviously taken by the authors.

Les traitements de l'hypertension arterielle

By MAURICE ROCH, Professeur de Clinique médicale a la Faculté de Geneve. Paris: Masson et Cie. 1934. Pp. 148. Fr.20.

IN this member of a series of monographs on clinical medicine and surgery, Prof. Roch divides cases of high blood pressure into two groups—concordant and discordant. The latter includes patients who have either a high systolic and normal or low diastolic, or a high diastolic and normal systolic reading. Discordant high blood pressure is always attributable to some cardiac cause, such as aortic regurgitation or congestive heart failure, and does not therefore come within the category of vascular hypertension.

The treatment of essential hypertension is considered in the light of various hypothetical causes such as infection, nervous factors, endocrine disturbances, renal lesions, &c. Prof. Roch points out that patients with malignant hypertension are beyond the scope of therapeutic measures. At the other extreme are those who are free from symptoms and require no treatment. It is the intermediate group with which the physician is chiefly concerned. In these cases, although we have no means of dealing directly with the underlying cause of the condition, much can be done to relieve symptoms and to prolong life. Rest and graduated exercise are the two most important measures; dietetic treatment is also important. Drugs are chiefly of value for dealing with the various complications which may arise, such as anginal attacks.

This little book gives a well-balanced account of the present state of our knowledge on its subject, and contains a large number of references to original papers published not only in France but also in other countries.

Aids to Public Health

Third edition. By W. G. AITCHISON ROBERTSON, M.D., D.Sc., D.Litt., F.R.C.P.E., Barrister-at-Law; late Lecturer on Forensic Medicine and Public Health, Surgeons Hall, Edinburgh. London: Baillière, Tindall and Cox. Pp. 208. 3s. 6d.

THIS is an elementary book on public health, dealing with the range of subjects usual in British publications of its kind—e.g., infection, disinfection, industrial hygiene, health of school and pre-school children and of mothers, food, housing, drainage and sewage disposal, atmospheric conditions, ventilation, lighting and heating, water-supplies, disposal of the dead, vital statistics, and sanitary administration. The class of student for whom it is intended is not clear, but it is readable rather than informative, and to school-children, for instance, this might be a recommendation. Unfortunately it contains several mis-statements. One is given the impression that trench frost-bite is a synonym for trench fever; that undulant fever caused by *Brucella melitensis* is becoming more common in this country; that contagious abortion of cattle is associated only with a similar condition in "human females"; that the Clayton apparatus is the usual means of ridding ships of rats; that every child entering school is mentally graded by school medical inspectors; that deficiency of vitamin A leads to rickets, and of vitamin D to scurvy; that one gramme of protein or carbohydrate yields 4·5 calories; that a dairyman must notify tuberculous cattle to the medical officer of health; that a usual standard of cubic space per patient in fever hospitals is 2500 to 3000 cubic feet; that water is usually chlorinated by bleaching powder; that an index death-rate and a standard (*sic*) death-rate are the same thing; that the "Comparative Mortality Figure" represents the corrected death-rate in each town compared with the recorded death-rate at all ages in England and Wales taken as 1000; and that there is some other "Occupational Mortality Figure" in general use. Enough has probably been said to indicate that the book is not suitable for serious students of public health.

Practical Endocrinology

Symptoms and Treatment. By MAX A. GOLDZIEHER, M.D., Endocrinologist, Gouverneur Hospital; Chief of Endocrine Clinic, Gouverneur and Brooklyn Women's Hospitals. London: D. Appleton-Century Company, Inc. 1935. Pp. 326. 21*s*.

Prof. Goldzieher teaches that an underlying veiled endocrinopathy should be suspected in all cases in which the symptoms observed are not satisfactorily explained on the basis of demonstrable pathological changes. He explains that in this book he sets out his personal concepts, and readily admits that some of the views upheld are not universally accepted. These introductory remarks convey a fair impression of the attitude and purpose of the author, whose work—short, simple, and dogmatic—is offered to the general practitioner. Most of the chapters deal with signs and symptoms, and being concise and practical, they will give considerable help to the doctor who, faced with a difficult case, wonders whether he is dealing with some obscure endocrine condition. The critical reader may feel that the endocrinopathies whose pathological basis is established should have been more sharply distinguished from those in which a particular endocrine origin for symptoms is inferred from analogy or circumstantial evidence. The chapters on treatment occupy one-sixth of the book, and they are, like the rest, a mixture of personal predilections with prevailing practice.

Die Folgen der Entmannung Erwachsener

By Prof. JOHANNES LANGE (Breslau). Leipzig: Georg Thieme. 1934. Pp. 177. RM.5.

THIS is an account of a follow-up investigation of 310 male adults who have sustained partial or complete loss of both testes (1) following war wounds (179 complete loss and 68 partial loss), and (2) following tuberculosis (63 complete loss). Their ages when examined by Prof. Lange ranged from eighteen cases under 35 to twenty-three over 55. Half were over 40. At the time when the injury was inflicted half of the cases were under 25. The investigation is based on a very full questionnaire of five pages, filled in by a doctor, asking some 200 questions under ten general headings.

Only a quarter of the cases were free from noticeable after-effects. Though the subjects of the investigation were not unduly affected by epilepsy, and were not predisposed by their injuries to endogenous mental disorders, and suffered comparatively little in social usefulness, it was established that potency was immediately or slowly extinguished in 112 out of 141 cases about whom information on this point was available, bodily changes of a eunuchoid character supervened in a majority of cases, and an appreciable proportion experienced attacks of giddiness sometimes amounting to fainting attacks, loss of vitality, and depression. The length of the period during which the patients were under observation has permitted the author to obtain interesting information upon the lapse of time between the infliction of the injury and the appearance of symptoms. Allowance is made for the fact that most of the subjects were in receipt of pensions, and for this reason did not minimise their disabilities. In general, the most noteworthy conclusion of the book is that the effects of castration vary to a surprising extent from individual to individual.

Eros and Psyche

An Essay on the Constitution and Destiny of Man. By BANCHARA BRANFORD. London: London University Press. 1934. Pp. 379. 12*s.* 6*d.*

Mr. Branford has a fine appreciation of Eastern and Western thought, and has done much to underline their common factors and their essential differences. This book is something more than an attempt to unite Eastern and Western thought; it is a philosophical treatise exhibiting a breadth of learning which will humiliate most readers. Unfortunately the manner of the writing is somewhat staccato, and the high degree of compression on each page makes the work difficult to digest. Those who have a philosophical bent and a background of considerable reading will find it attractive and even stimulating.

Une nouvelle syphilis nerveuse

By PAUL RAVAUT, Membre de l'Académie de Médecine; Médecin de l'Hôpital, St. Louis. Paris: Masson et Cie. 1934. Pp. 196. Fr.45.

Dr. Ravaut tells us that as long ago as 1903 he reported his first series of cases of latent neurosyphilis, that is to say, cases of syphilis in which there were no clinical signs of involvement of the central nervous system and in which the condition could only be recognised by routine lumbar punctures. By following up the cases over a number of years he has ascertained that many of them may completely clear up, whereas others are the precursors of clinical neurosyphilis. The importance of early diagnosis is stressed, because the earlier the cases are treated the more likely is the involvement of the central nervous system to be eradicated, either by chemotherapy or by malaria therapy or by both. It would have added considerably to the value of the book if details of treatment had been given; for example, as regards the comparative value of trivalent and pentavalent arsenic, silver salvarsan and neo-silver salvarsan, bismuth preparations, intrathecal injections, and so forth; Dr. Ravaut has pursued his studies of the subject for over 30 years, and he notes with satisfaction that investigators in France, Germany, and America have confirmed his original observations. He makes no reference however to the important investigations of P. Fildes, R. J. G. Parnell, and H. B. Maitland upon 1314 cases of syphilis among naval ratings, the results of which were published in 1920 by the Medical Research Council under the title "Unsuspected Involvement of the Central Nervous System in Syphilis." These observers found 28 per cent. of their cases to have abnormalities of the cerebrospinal fluid, and they concluded that more definite evidence must be produced before Ravaut's statement that 62 per cent. of cases of secondary syphilis have abnormal central nervous systems could be accepted without reserve.

The changes that may be found in the cerebrospinal fluid are fully described and stress is laid upon the types of cell—the most important being the plasma cells. A coloured plate shows well the appearances of the cells as stained by methyl-green-pyronin (Unna-Pappenheim); by means of the type of cells it is possible to distinguish between the meningovascular and the meningo-parenchymatous forms of neurosyphilis. Dr. Ravaut has done well to collect into one book the results of his extensive researches.

Black's Veterinary Dictionary

Second edition. By WM. C. MILLER, M.R.C.V.S., F.R.S.E., Courtauld Professor of Animal Husbandry in the Royal Veterinary College. London: A. and C. Black Ltd. 1935. Pp. 1141. 21*s.*

Black's Veterinary Dictionary is already well known to those who handle animals, and a new edition, incorporating some of the advances in knowledge which have been made during the last seven years, will be welcomed. In general plan the book resembles Black's Medical Dictionary. Animal management and hygiene receive considerable attention, whilst disease is treated in such a way as to increase the reader's general knowledge and help him to render appropriate first-aid treatment. At the same time it encourages coöperation between the layman and the veterinary surgeon. Fourteen other workers, including some of world-wide repute such as Prof. F. A. E. Crew and Prof. R. G. Linton, have assisted by contributing special articles.

Considerable effort has been made to make this publication comprehensive and useful by extensive cross-indexing, but even now there are some omissions which will affect particularly the non-professional reader. A detailed chapter on dog management and a more extensive index of popular agricultural terms would be useful additions. Prof. Miller has maintained a high standard on all subjects appertaining to animal management and animal hygiene; sections dealing with diseased conditions follow orthodox teaching. With regard to the more specialised subject of bacteriology, the presentation is less satisfactory. In an attempt to render the subject simple, the author and his collaborator have sometimes caused confusion. For instance, steaming for thirty minutes on three successive days is the only method of sterilising medium which is recorded (p. 80). In a table dealing with nomenclature (pp. 1089–1090) bacteria are for some obscure reason tabulated alphabetically, the nomenclature of the American Society of Bacteriologists being adopted. As a result, closely allied organisms such as the typhoid bacillus (Eberthella) and *S. enteritidis* are separated from one another by leptospira, mycobacterium, and other genera. Furthermore, B C G is given generic significance, the name botriomyces is still used for staphylococcus when that organism causes a granulomatous lesion, pasteurella are still classified according to the zoological species of the host, and *Vibrio septique* is given as an appropriate example in the definition of the word vibrio. The unqualified statements (p. 1089) that *Actinobacillus lignièresi* causes actinomycosis and *Leptospira icteroides* causes yellow fever in the human being are misleading.

Taken as a whole, this publication is an excellent piece of work which will bring credit to the author and publisher, and will be of immense value to stock owners throughout the world.

THE LANCET

LONDON: SATURDAY, APRIL 20, 1935

THE POSITION OF OSTEOPATHY

The most recent attempt to obtain State recognition for the cult of osteopathy came to an ignominious conclusion when, at the meeting of the Select Committee of the House of Lords on April 12th, Mr. J. H. Thorpe, K.C., leading counsel for the promoters of the Bill, opened the twelfth day's business by announcing the decision of his clients to proceed no further with the Bill. Two reasons were given by Mr. Thorpe for this unexpected withdrawal. In the first place, he said, it had become clear during the meetings of the Committee that the issue had changed; it was now not so much the desirability of the registration of osteopaths and the regulation of the practice of osteopathy, as the question whether osteopathy could be said to rest upon a scientific basis. This was a matter in which he found himself out of his depth, and on which, "speaking with great respect," it was beyond some of the members of the Select Committee to make a finding. The second reason for the withdrawal was the position of the British School of Osteopathy, an essential feature of the Bill. The promoters felt that they would not be justified in asking for the passage of a Bill which was so intimately bound up with the continuance of this school. So far few will be found to differ from Mr. Thorpe, though many may wonder whether the promoters of the Bill will appreciate the full implication of his remarks. It was the remainder of Mr. Thorpe's speech which aroused an immediate reaction, for he went on to plead, apparently with the concurrence of Lord Elibank, who introduced the Bill in the House of Lords, that the Select Committee should recommend that a Royal Commission, or some equally responsible body, should be set up to inquire into the scientific justification for the theory of osteopathy. Very naturally counsel for the opposing bodies strongly objected to this suggestion. They pointed out that if their lordships proposed to make such a recommendation it was incumbent on them to continue the hearing, since expert witnesses, who had studied the so-called scientific evidence produced, were prepared to say that there was no acceptable evidence before them that osteopathy rested on any scientific basis at all. After considerable argument their lordships debated in camera and then decided to hear two more witnesses of their own selection and to leave it at that.

By an adroit manœuvre the osteopaths have extricated themselves from a difficult position, but we think that a claim made by their counsel that the battle is drawn will meet with little support from the general public. In no contest can the side which breaks off hostilities claim an equal position with opponents who desire to go on. Let us consider the position at the end of the eleventh sitting of the Committee. The representatives of osteopathy had had a clear field, and for some weeks the lay press had been full of the osteopathic theory and the osteopathic lesion. Osteopathy and manipulative surgery, often confused during the sittings, were hopelessly muddled up in the reports; in any argument defence of theory gave way to defiant support of practice as the needs of the moment demanded, and prejudice and bias were freely ascribed to every medical witness. Gradually, however, the issues before the Committee became defined, and now the claims for a scientific basis for osteopathy came up to be examined. Mr. H. S. Souttar, the last clinical witness to be called, had given his trenchant evidence-in-chief and was awaiting cross-examination, and it was known that he was to be followed by experts in various fields, notably pathology, physiology, and anatomy, whose special function was to report on the "scientific" writings on which such stress had been laid. And this was the moment chosen to break off the contest. To the surprise of all who throughout the sittings of the Committee had admired his gallantry and skill, Mr. Thorpe, having made no attempt to combat Mr. Souttar's challenge of fraudulence, threw overboard any defence of the seven Bulletins of the A. T. Still Institute for Research and the rest of the evidence supplied with such impressive zeal by Dr. Macdonald. It is really no explanation for the remarkable course of action to say, as Mr. Thorpe did, "I should like to recall that it is the osteopaths, with the assistance of a noble lord, who have come into the open, who have urged the presentation of this Bill in Parliament; they have satisfied, at any rate, one noble lord, and they are ready to submit with confidence to any issue that is to be decided hereafter by an impartial tribunal." For what does this amount to? We hesitate to suggest that the noble lord was biased, but he accepted a Bill whose main structure required the existence of an institution which has since been entirely discredited; and he attempted to pass through Parliament a Bill which would give legal status to practice founded on a doctrine on the justification for which it is said to be "beyond" a selected group of his fellow legislators to express an opinion. If to try to rush Parliament in this way is to be regarded as a meritorious act, then indeed osteopathy emerges with flying colours from the inquiry. But we prefer to believe that saner opinions will prevail, and that the report of the Select Committee will show that

> ". . . noble statesmen do not itch
> To interfere with matters which
> They do not understand."

THE HEART IN SCARLET FEVER

In scarlet fever of the fulminating type, now rarely encountered, the cause of death may be an acute toxic myocarditis; but the cardiac lesion most often seen in this disease is an endocarditis—sometimes associated with pericarditis—which becomes manifest in the later stages. FAULKNER, PLACE, and OHLER[1] point out that the existing clinical descriptions of "scarlatinal endocarditis" do not agree with one another and that the diagnosis of acute endocarditis in the presence of infection may be very difficult. They are inclined to doubt the quantitative value of the various estimates of its incidence, some of which they quote. Thus J. F. H. BROADBENT (1908) in an analysis of 22,096 cases of scarlet fever found 129 (0·58 per cent.) examples of endocarditis, and A. JOE (1924) reported 61 (0·25 per cent.) with endo- or peri-carditis in a series of 24,102. It may be added that in another analysis ZISCHINSKY,[2] examining 20,000 records of scarlet fever (1902–29), could find only 10 (0·05 per cent.) with evidence sufficient for a diagnosis of endocarditis. In the 7 which proved fatal an "infective" or malignant lesion was found post mortem, while of the 3 which recovered, 2 had had undoubted acute polyarticular rheumatism late in the attack and only 1 had residual mitral insufficiency which could reasonably be ascribed to scarlet fever alone. These analyses are based on records made in different cities (London, Edinburgh, and Vienna respectively) and the material analysed is ample enough to eliminate chance. The difference in the incidence of endocarditis which they reveal is to be ascribed not to defective diagnosis but to variation in the type and severity of scarlet fever and its consistent trend, over the period represented, towards increasing mildness.

FAULKNER and his colleagues have looked at the problem from two angles: they have made electrocardiograms during the acute phase and then have inquired into end-results in the form of chronic valvular disease. During 1932–34 an electrocardiographic study was made of 171 cases of scarlet fever of "relatively mild" character, during and following the acute infection; except that all cases of scarlatinal arthritis were included, no other selection was made. Of these 171 patients, only 11, whose ages ranged between four and sixteen, developed abnormal records; in 5 there was a prolongation of P–R, and in 6 a flattening or inversion of T. There seemed to be no relation between the severity of the illness and the incidence or degree of electrocardiographic abnormalities. Nor were the electrocardiographic and clinical findings altogether consistent: for in 5 cases in which the record was abnormal there were no physical signs, and 3 others had only systolic murmurs; while 17 patients whose records were normal had systolic murmurs (though without other evidence of valvular damage). It was noteworthy also that the abnormality never appeared before the thirteenth day from the onset of scarlet fever, and the authors compare this delayed reaction with the recrudescence of acute rheumatism after a respiratory infection; in 5 of their cases, moreover, the electrocardiographic manifestations coincided with a return of fever. In the second part of their inquiry 600 patients of an average age of 6·3 years were examined 1–3 years after they had been in hospital with scarlet fever. Only 7 were found to have developed signs of chronic valvular disease, but in 2 of these there had been signs before discharge, while 2 others had had rheumatic fever in the interim. In the remaining 3 there was no antecedent history of rheumatism or chorea to account for the valvular disease, and the lesions were indistinguishable clinically from "rheumatic" heart disease. Contrary to the general view, FAULKNER, PLACE, and OHLER did not observe that an attack of scarlet fever lights up an existing quiescent rheumatic cardiac lesion; thus among the 171 cases examined by electrocardiograph during their illness there were 6 with old rheumatic lesions, and only 1 of these had signs of reactivation. Their general conclusion is that all the findings in the acute and late phases of cardiac involvement in scarlet fever are similar to those seen in rheumatic fever following acute tonsillitis. In both conditions there is often a well-defined latent period between the respiratory infection and the secondary constitutional reaction, and in both of them endocarditis may occur with or without an acute migratory arthritis. They believe we are now justified in saying that rheumatic and scarlatinal heart disease are probably identical, and that upon the allergic hypothesis "a properly sensitised individual may respond to an infection with *Streptococcus scarlatinæ* by the allergic reaction known as rheumatic fever." There is no evidence, they add, that this reaction differs significantly from rheumatic fever following other streptococcal infections of the upper respiratory tract.

Most clinicians in this country would agree that, whatever the pathogenesis, the acute polyarthritis of simple scarlet fever is "rheumatic"; but they would incline to the view of HECTOR[3] that "the almost invariable result of scarlet fever upon the heart already damaged by rheumatism is a re-kindling of the old trouble."

CHILDBIRTH AT HOME OR HOSPITAL?

Is the home or the hospital the best place for a confinement? Of recent years there has been a much wider provision and use of maternity beds in hospitals and other institutions, and the fact that during the same time the maternal mortality-rate has increased naturally raises doubt in many minds as to the possible connexion between the two. Conflicting views on this question were put forward at a discussion on maternal mortality at the Royal Sanitary Institute on April 9th. Mr. EARDLEY HOLLAND, who opened the discussion and whose remarks are briefly reported on p. 936, held that the prime cause of a high maternal mortality was insufficient training of the medical profession, leading to meddlesome midwifery. He compared the situation to the British Admiralty sending a battleship to sea with an amateur crew, and suggested that the Rochdale experiment[4] —in which the maternal mortality-rate for the years 1929–31 of 8·90 had been reduced to 2·99 for the three subsequent years by a campaign to make the public and the midwives and doctors (as it was put) obstetrically conscious—proved his contention. Dr. Andrew Topping, under whose auspices as medical officer of health the experiment had been initiated, confirmed Mr. Eardley Holland's view that the previous high rate was caused by too much midwifery, and that the improvement was due entirely to a change of outlook, the expectant mother and her relatives having been educated not to bring pressure to bear on the medical attendant to hurry things up. Another factor was that the doctors sent cases with complications into hospital earlier and the number of failed-forceps cases had been greatly diminished. Dr. W. H. F. Oxley suggested that it was not so much lack of training as the conditions under which he had to work that drove the medical attendant to interfere too much; but since the pressure towards interference is largely removed in confinements in institutions, his plea for confinements to take place at home seemed illogical unless the whole country is to be educated on the Rochdale lines. Dr. R. Veitch Clark (of whose remarks a summary also appears on p. 936) gave, indirect support to the plea for more institutional confinements when he showed that the average number of confinements attended by practitioners in Manchester was only two and a half per annum, and that out of 110 practising midwives only 32 were dependent wholly on their professional earnings for their maintenance. How, he asked, could such a very part-time service be efficient? More than half the confinements in Manchester take place in institutions, but Dr. Veitch Clark would encourage domiciliary confinements by limiting the number and thus improving the practice of midwives, on the lines of the recent report of the Joint Council of Midwifery.[5] Sir Francis Fremantle contributed to the discussion by foreseeing Parliament's willingness to pass even restrictive and costly measures if satisfied that they would have the desired effects.

Everyone agrees that provision of beds for abnormal cases must be adequate, and that there is still a lack of beds for antenatal cases requiring observation and treatment. But, with the undoubted additional risk from outbreaks of sepsis in institutions, is the costly provision of beds for a high proportion of normal cases justified? Dr. George Buchan, who presided at the meeting, considered that the women themselves have already answered the question by their increasing demand for confinements in institutions; but it must be remembered that in the U.S.A., where domiciliary confinements are almost unknown, the maternal mortality-rate is higher than in this country and is also increasing. Nor is the risk of unnecessary operative interference entirely removed, at any rate for private patients, by confinements in hospital, since in one hospital in Philadelphia we learn [6] that "in a period of six months an operative incidence of 50 per cent. was shown on the private floor service as against 4 per cent. in the ward service." Whether the normal case is to be confined at home or in hospital, it will still be necessary to improve the training and practice of the doctor and midwife, and to educate the public against needless interference. But there must clearly be other factors involved, as the story of the so-called 'black area shows. For at least 50 years these areas have had a rate substantially higher than the rest of England, and no one would suggest that the doctors, midwives, or public in Wales and north-west England are less fully educated than others or less conscious of their responsibilities. Perhaps the investigations now being undertaken by the Ministry of Health will bring to light this unknown factor.

FUNCTIONS OF LYMPHATICS

Our knowledge of the lymphatics and of the part played by them in maintaining the circulation has lagged far behind that relating to the vascular system. This is doubtless due in part to technical difficulties in making direct observations upon lymphatic capillaries. Recently S. Hudack and P. D. McMaster [1] described a delicate technique by means of which living peripheral lymphatic trunks and capillaries are made visible. With a dissecting microscope and micro-injection apparatus, India ink and various dyes may be injected into the ears of albino mice illuminated by light reflected from white porcelain plaques. These authors have applied the method chiefly to a study of permeability of lymphatic endothelium and to the behaviour of lymphatic channels damaged by incisions and burns. When carbon particles have been introduced into them, the lymphatic channels can be effectively photographed by reflected or transmitted light. Using the same method, B. D. Pullinger and H. W. Florey [2] show clearly by sets of photographs taken with the mouse's ear placed on the end of a total reflection rod that injection of hydrokollag containing 1/5 pituitrin (Parke, Davis and Co.) or 1/5000 adrenaline causes no contraction of the lymphatic capillaries, although when the drug escapes into the surrounding tissues it causes a marked contraction of the arteries. Nor does mechanical stimulation of the tissues produce any active response by lymphatic capillaries. The walls of the lymphatics are elastic and can be distended by moderate pressure without sign of rupture or leakage of hydrokollag particles.

An interesting development of the work concerns the part played by the lymphatics in œdema, whether inflammatory or otherwise. It is known that lymphatics are dilated in inflammation, and this is of moment when it is considered that the pressure within them is lower than that in the surrounding tissues. Pullinger and Florey found by injecting the tissues of the mouse's ear with saline, with histamine 1/1000, or with calcium chloride, after filling the lymphatic capillaries with hydrokollag, that dilatation of these vessels was maintained and the accumulation of fluid in the tissues did not compress them. Histological studies of the specimens used for these experiments, and of suitable controls in which hydrokollag had been omitted, suggested that the lymphatic channels are held open by the connective tissue fibres which are attached in considerable numbers to their walls. The dilatation therefore would appear to be of a passive nature.

ANNOTATIONS

THE METROPOLITAN POLICE LABORATORY

THE opening of the Metropolitan Police Laboratory at Hendon last week was an occasion of real significance. It was an expression on the side of the law of a determination to combat the forces of crime, recognising that those forces had grown more difficult to withstand since the criminal had learnt to enlist science on his side. Everybody is familiar with the activities of those admirable amateur detectives Sherlock Holmes—it is not remembered at the moment whether he had any academic standing—and Dr. Thorndike. No doubt for the purposes of the story the authors, both medical men, assumed that their heroes were masters of matters in connexion with forensic medicine to an extent that no ordinary man of law or ordinary man of medicine could be. Of course this assumption was quite unjust. It has always been the routine in police procedure to carry out, as far as up-to-date knowledge permitted, the intensive researches which Conan Doyle and Austin Freeman attributed to their super-investigators, make scrupulous examinations of the dead body, and of all surface markings and skeletal characteristics. Again, the examination of blood and other stains, and of premises or fomites connected with a possible crime, in order to obtain evidence, has always been conducted by the police authorities, and treatises on forensic medicine give much information on the procedures. But to the rank and file of the constabulary most of this was unknown, even while the necessity for observation of all that might have relation to the circumstances of a crime was complied with. The Metropolitan Police Laboratory will bring this knowledge nearer to the general body of policemen by creating a class of inspectors as experts on the scientific investigation of crime.

The students at the new laboratory will not be taught elaborate physiology, toxicology, and so on. The intention is to create for the metropolitan area a laboratory which can be used for training selected students for scientific work in connexion with criminal cases as they come to the notice of Scotland Yard. Similar institutions to the one now started in London are already at work in Edinburgh and Glasgow, and the need for a laboratory had been for some time felt in London. The school is starting with 60 students whose claims for the special training have been suitably investigated, and among them are young police officers of promise and experience, and recruits from various universities. A certain rank in the constabulary is given to these cadets, whose pay suffices to discharge their comfortable accommodation and an adequate mess bill, while they remain to this extent on probation, that at the conclusion of the course they will have to sit for a passing-out examination. The curriculum, which is under the direction of Dr. James Davidson, lately pathologist to the Royal Infirmary, Edinburgh, includes (among other things and mainly) instruction in an adequate amount of anatomy and physiology, in chemistry and microscopy, the lessons here being directed almost exactly to those difficulties, the explanation of which leads to the acquittal in detective novels of apparently incriminated persons.

The laboratory will, it is hoped, prove a stimulus to the institution in suitable places throughout the country of similar laboratories, and two or three of our large provincial centres have already started work on these lines.

ASTHMA

Sir Humphry Rolleston has summarised[1] the work of the Asthma Research Council since its constitution in 1927 and adds a bibliography of publications by the Council's research workers and medical advisory committee (1928–34). It is interesting to read the original programme of research in the light of subsequent developments. Good work has been done in describing more clearly the natural history of asthma, its relation to other allergic disorders, its constitutional basis, and its prevalence. The value of respiratory exercises and the importance of psychological factors in the disease have been clearly brought out, and this is probably the chief contribution made to therapeutics. In the majority of cases asthma begins in childhood, and at this period, before the asthmatic habit has become ingrained and gross damage has been done to the respiratory system, there is a reasonable chance of arresting it by breathing exercises and by the removal of psychological stimuli. Nothing very novel has come from the study of the parts played by nasal abnormalities, by protein sensitisation, and by bacteria and other organisms, for these had been exhaustively considered by previous workers; indeed, it seems unlikely that further striking progress will be made on these lines. The origin and significance of "urinary proteose" remain obscure. It is surprising that so little has been done to study the effects of diet in asthma, for lay members of the Council expected great results from this, and though the difficulties of dietetic experiments on ambulatory patients are great, they should not be insurmountable. The pharmacological side also seems to have been neglected, except for studies on the relative merits of ephedrine and pseudo-ephedrine, and experiments with dioxyphenylalanine. Quite apart from research on new synthetic or pharmacological principles akin to adrenaline and ephedrine, there is an obvious need for clearing the jungle of symptomatic remedies for asthma, in the same way that the therapeutics of heart disease and anæmia have been rationalised in the past few years. It should also be relatively simple to discover what drugs can best be combined with ephedrine to prevent the unpleasant side reactions so common with this drug. There are more than enough patients for controlled clinical investigations of this kind, which seem likely to offer a better return than highly technical methods of preparing vaccines or grape-shot mixtures of antigens for inoculation.

MEDICAL TREATMENT OF GLAUCOMA

IT is generally held by ophthalmic surgeons that non-operative treatment of glaucoma is unreliable and should only be resorted to either as a preliminary to operation or in cases where for one reason or another operation is impracticable. But this opinion is not universal. Prof. G. H. Burnham of Toronto has recently advocated[2] his "combined treatment" as a substitute for operation in most cases, and many surgeons have succeeded in arresting the progress of the disease in very chronic cases by the continued use of eserine. Some years ago it was discovered that adrenaline has the power of diminishing intra-ocular tension, and Carl Hamburger of Berlin had some success with a related drug, called Lævo-glaucosan, which, although it dilates the pupil, has the property of bringing down intra-ocular tension. Josef Böck, writing[3] from the University eye clinic of Vienna, deprecates the use of this and other drugs such as histamine which cause so much chemosis as to make operation, if it should be decided on, more difficult. The intravenous injection of hypertonic solutions of salt or sugar, which have also been recommended to bring down the tension, may cause collapse in elderly patients. The only reliable palliative is the time-honoured treatment by drops of eserine or pilocarpine, carefully regulated as to strength and time of administration according to the particular needs of the patient. In a more recent paper in the same journal[4] Hamburger, whilst admitting that his first hopes from glaucosan were too optimistic, still claims that this drug is indispensable in the treatment of certain cases of secondary glaucoma—viz., those due to iritis in which dilatation of the pupil may be desirable, and any operation on the iris is likely to fail. He also claims successes in cases where an operation for glaucoma has failed to cure. Böck replies[5] that his remarks applied only to primary glaucoma. At the same time he doubts the utility of glaucosan in any case. There are certainly cases in which it gives rise to more pain than can be tolerated.

THE PREVENTION OF DIPHTHERIA

DURING the last fifty years the death-rate from diphtheria has been more than halved. In the quinquennium 1876–80 the death-rate from diphtheria and croup was 726 per million children at ages under 15 years; in 1926–30 the rate was 302, or but 42 per cent. of the level recorded half a century previously. So great and satisfactory an improvement must not, however, lead to an attitude of complacence. Absolutely diphtheria is still one of the important killing diseases of childhood—in the five years 1928–32 there was an average annual total of 3000 deaths attributed to it, while at the present time the country is passing through an epidemic with an incidence considerably above the average of the past decade. Relatively as well the position is not one for complete satisfaction. While noting that diphtheria has fallen by 58 per cent. in fifty years it must be observed that over the same period of time the death-rate from measles fell by 64 per cent., from whooping cough by 73 per cent., and from scarlet fever by 97 per cent. Of the four major infectious diseases of childhood diphtheria has declined the least. It is clear that methods of prevention energetically pursued may gain substantial rewards, and there is little doubt that artificial immunisation universally adopted offers the most hopeful means of securing them. Some of the evidence in favour of immunisation is presented by Sir Leonard Rogers in the current number of *The Fight Against Disease*, the quarterly journal of the Research Defence Society. From Graham Forbes's monograph[6] he tabulates the results of inoculation of the staffs of various diphtheria isolation hospitals, for this he regards as the most severe test immunisation can be put to, since nurses are exposed to grave danger of infection from the cases they attend intimately and for long hours. Clinical attacks are, naturally enough, sometimes recorded amongst the "protected," but such cases are invariably mild, while in addition nearly every hospital reports an appreciably lower incidence since inoculation of their staff was undertaken. From children's residential institutions there is also abundant evidence that by systematic Schick-testing and inoculation the incidence of diphtheria can be greatly mitigated or almost abolished. The classic work, which Sir Leonard Rogers quotes in some detail, is that of Sheldon Dudley at the Greenwich Hospital School. Here, between 1919 and 1927, there was an annual yearly average of 42 cases; since inoculation there have been only 4 cases in four years, three of which were in "unprotected" children. There seems no doubt that if we could extend immunisation to the majority of the child population the death-rate from diphtheria would show a further substantial decline.

In one particular we must correct Sir Leonard Rogers. He states that "diphtheria is only second to measles as a cause of mortality from children's infectious diseases." He has overlooked whooping-cough, which in every quinquennium from 1866–70 to the present time has shown a considerably higher death-rate than diphtheria and, indeed, in 1921–30 was as a cause of mortality the leader of the four major infectious diseases of early life.

HOSPITAL ADMINISTRATION FOR ALL

THE extent of responsibilities shouldered severally by the superintendent, the matron, and the secretary of a large hospital tend to vary somewhat with the personalities concerned, with their relative length of service and with local tradition. Whatever the distribution of authority, it is of the utmost importance for smooth running that each should know something of the organisation of the departments controlled by the others. For this reason, among others, a book[1] by Miss E. MacManus, matron of Guy's Hospital, entitled "Hospital Administration for Women," will be useful also to men. A light touch and an approach which invites friendly interest conceals the fact that an extraordinary amount of detailed information, largely unobtainable elsewhere, has been packed into its six sections. The first of these deals with personal and central administration and is subdivided into chapters on the work of the superintendent's office, the duties and responsibilities of the matron, and the functions of the various committees generally appointed by the Court of Governors of voluntary hospitals. (The corresponding organisation of a municipal hospital is more briefly stated in an appendix.) In this section a scheme is outlined for a nurses' representative council of 15 members, including the matron, 12 members being elected by probationers and 2 by staff nurses. Such a council, which is established at Guy's and at certain other hospitals, affords the nurses opportunity for making representations affecting their well-being and education, which is greatly appreciated. Matters of personal conduct and discipline are, we understand, specifically excluded from discussion. The following section of the book is devoted to the nursing staff—the administrative hierarchy being clearly defined and their duties in a large hospital of 600 beds described with precision. The chapter on the home sister and the nurses' residence gives explicit directions for methods of promoting the nurses' comfort and convenience in sickness and in health. It is noted that the provision of one definite place where nurses may smoke clears the air figuratively, if not actually. The ward sister, "arbiter of her small kingdom," is shown in her various capacities: accompanying the house officer on his rounds and carrying out the treatment ordered; feeding the patients; teaching the nurses; keeping the ward orderly and dealing calmly and without fluster with special situations, including anything from confiscation from patients of razors and knives or illicit drugs, and detection of faked pyrexia, to discrimination between two or even three wives who claim the right to sit by the bedside of a dying man. This last situation, as Miss MacManus observes: "requires the wisdom of Solomon, for the obvious solution is rarely the right one, and the legal solution is rarely the happy one." If the patient is conscious, she adds, his wishes should be carried out; it is when he is unconscious that the ward sister's ingenuity may be taxed.

[4] Ibid., March 15th, 1935, p. 335.

[5] Ibid., p. 336.

[6] Diphtheria, Past and Present. London. 1932.

[1] Hospital Administration for Women. By Emily MacManus, Matron, Guy's Hospital, London. London: Faber and Faber. 1934. Pp. 356. 15s.

The chapters on the nurses in training and already trained, and the preliminary and hospital training school in Section II show, as would be expected, an intimate knowledge of the complex task of organising the curriculum of a group of young women whose preparation for entry, after examination, to a State register must include previous experience in every important department of the hospital, as well as attendance at lectures and demonstrations. Schedules of quarterly changes of posts, rotas of off-duty times, charts showing distribution of work and time-tables of lectures and classes are set out and will assuredly prove useful to less experienced administrative officers. Section III deals with the domestic staff, including porters; Section IV with works, central power station, laundry, linen stores, dressmaking department, steward's stores, hospital kitchens, catering, and the dispensary; and Section V with schools and associations connected with the hospital, such as schools of massage, medical electricity and actinotherapy, radiography, midwifery, and almoning, as well as with antenatal and postnatal departments, the infant welfare centre, and voluntary workers.

We have already hinted that the title of this work is too modest, and should add that less than half is devoted to the nursing side of hospital life. Almost anyone concerned in hospitals—from the senior member of the consultant staff to the junior recruit in the secretary's office—will do his work the more efficiently if he not only reads it, but keeps it by him for frequent reference.

A NEW HOME FOR THE B.D.A.

THE official opening of the new home of the British Dental Association, described in our news columns, is a proper occasion to recall the part which the Association has played in the progress of dental science and practice. Sixty years ago the conditions under which dentistry was practised in this country were becoming intolerable to those who had the welfare of the profession at heart, and a Dental Reform Committee was formed whose labours culminated in the passing of the Dentists Act of 1878. Their preparatory work done, this body resolved itself into the representative board of the British Dental Association which was finally incorporated in 1880. The first work of the new Association was a scrutiny of the credentials of applicants for admission to the Dentists Register, and this laid bare the fact that the Act had in it a fatal flaw which as the years passed became a menace, only to be removed by the Act of 1921, which finally closed the door to any one who had not passed through the schools and obtained a dental diploma. The Association, which started in 1880 as a centralised body with a membership of 120, had increased its membership by 1884 to 600 by attracting five provincial societies as branches. Branches and membership have grown until there are now 16 branch areas, each divided into sections, with a total membership of 4239, affording opportunities throughout the country for the cultivation of scientific study and social intercourse. Through this organisation broad lines of policy can be submitted to members and a prompt decision reached. The Association has not only raised the profession of dentistry; it has behind it a long record of public dental service, both practical and educative in the popular sense. Fifty years ago there was no school dental service, indeed little of any kind. In 1883 the Government of the time declined to recognise oral hygiene even as coming within the scope of an international health exhibition. The school dental service, imperfect though it still may be, owes its development entirely to the efforts of the Association. Adult dental health has not been disregarded, and when *additional dental benefit* was instituted the Association prepared a comprehensive scheme of public service making dental treatment available to millions. Persistent representations to the departments concerned have seen fruit in the present complete dental service now provided for the Navy, Army, and Air Forces. All these advances can be studied in the *Journal* of the Association which in March, 1880, took over the *Monthly Review of Dental Surgery*, and has since 1903 been known as the *British Dental Journal*.

MURK JANSEN

THE death of Dr. Murk Jansen, of Leyden, at the age of 67, has deprived orthopædic surgery of one of its outstanding leaders. Jansen was born at Zaandam and came of a line of schoolmasters, but at an early age expressed a desire to choose medicine as his future career. Loyalty to family tradition, however, compelled him to become a teacher of English until the age of 25, by which time he had accumulated sufficient funds to enable him to enter the University of Leyden as a medical student. He graduated in 1900—he was then 33—and for the next four years acted in turn as prosector in anatomy and assistant in the surgical clinics of Leyden and Amsterdam. His interests soon became directed towards orthopædic surgery, and, after settling in practice in Leyden, he was appointed lecturer in this subject in his old medical school. Jansen soon acquired one of the largest private practices in his specialty on the Continent, but he never allowed material success to deflect him from an unceasing inquiry into the science of orthopædics. Aided by an amazing mastery of foreign languages, his unorthodox views on bone formation and on the origin of congenital deformities became known far and wide. Through his regular visits to other countries, Jansen acquired a circle of devoted friends who were attracted both by his powerful intellect and by his innate charm and culture. Amongst his earliest friends in this country were Prof. (now Sir Grafton) Elliot Smith and the late Sir William Thorburn, of Manchester. Later he came under the spell of Sir Robert Jones, which ripened into affection. During the war, when a considerable

number of British wounded became interned in Holland, the Dutch Government applied to our War Office for the services of an orthopædic surgeon. This request was passed on to Jones, who had the pleasure of informing the Dutch Government there was in practice at Leiden one of the most distinguished of living orthopædic surgeons. For his services to our wounded Jansen was awarded the O.B.E. In his earlier efforts to get recognition for orthopædic surgery as an autonomous specialty in the Dutch medical schools Jansen met with strenuous opposition. But he was by nature an uncompromising fighter in any cause in which he believed, and he refused to bow. In 1920 he founded in Leyden the Society for the Deformed, and in 1928 he gave half his private fortune to build and equip a hospital of 60 beds, known as the Anna Kliniek. Before his death Jansen had the satisfaction of knowing that this hospital had been recognised as the *official* teaching clinic in orthopædic surgery of the University of Leyden. In the same year the Dutch Government conferred upon him the honour of the Knighthood of the Lion. In 1933, on the death of Sir Robert Jones, Jansen succeeded him as president of the International Society of Orthopædic Surgery. The generous hospitality of Jansen and his wife on the occasion of the meeting of the British Orthopædic Association at Leyden last year will be long remembered.

NASCITUR RIDICULUS MUS

THE name of Mickey Mouse drew large and excited crowds to the Royal Society of Medicine last week, and it was once more evident that the medical profession and its wives are only human after all. To serious workers, perhaps, a first disappointment was the discovery that Mr. Robb Lawson, though billed to speak on the anatomy and embryology of the said mouse, was neither anatomist nor embryologist: we were to get no erudite satire on methods current in these sciences. By way of compensation came an illustrated account of Walt Disney's studio technique, and four marvellous films—two Silly Symphonies and two Mice. Mr. Lawson tried to find a sociotherapeutic purpose in these impossible creations, and Dr. Robert Hutchison, in introducing him, compared Mickey to the celebrated Dr. Merryman. It would have been no exaggeration that evening, however, to speak of him as Dr. Riot;[1] for certainly (as he said later) the Barnes Hall has never resounded to such mirth; and we fear the next distinguished lecturer there—even if he provides himself with fly-papers—must expect to fall a little flat after Playful Pluto. As for the embryological aspect, Mr. Lawson kept just enough back to prevent any of us setting up immediately in opposition to United Artists. His audience learnt all about the need for team-work and the troubles of musical directors; they heard about the three kinds of artists and the functions of those who merely copy with a difference; and they were brought to realise the necessity of thinking up plenty of good gags. It was divulged that all the mobile figures are drawn on transparent sheets placed one above the other; they are then photographed and changed where necessary, the background remaining the same; and all this involves some 10,000 exposures for a short film. The truth is that the photography and everything else takes so long that it really seems best to leave the business in the hands of those who like doing that sort of thing. Meanwhile, it is comforting to learn that medical practice is not the only occupation in which success depends on collaboration. No doubt the journals of the Mickey Mouse industry, like those of medicine, constantly contain moving appeals for closer coöperation between the artist, the animator, the artist-animator, and the odd-job man.

A "CAUSE" OF EPILEPSY

SIEVEKING is credited with the statement that there is no substance that can pass down the gullet of man that has not at one time or another been considered a specific for epilepsy. The list of alleged causes of this disorder may not be quite so comprehensive as the list of cures, but its diversity is about as great; and most of the items on it would be better defined not as causes but as factors in the determination of attacks in potential epileptics. And now we have Dr. Pagniez with a convincing account of a brand new one.[1] After a fall on the head a boy had a few typical epileptic fits, followed by several years' freedom. He then began to get attacks of giddiness, headache, and nausea, the nature of which was made clear by the occurrence of a typical major attack of epilepsy. Rigorous examination disclosed nothing abnormal in the nervous system or elsewhere, and dietetic factors were investigated and excluded. After long months of medicinal treatment, which produced amelioration but not cure, the patient one day called Pagniez's attention to his wrist-watch and other silver articles which were always turning black. A search for abnormal sulphur absorption from the alimentary canal was fruitless, but eventually it turned out that the patient had been for some time using a sulphur lotion on his head to prevent his hair falling out. The lotion was promptly stopped; the silver articles ceased to tarnish; and the epileptic manifestations disappeared. It is difficult to doubt the cause and effect suggested in this story, but it is important to recognise that here was a potential epileptic of a high degree of potentiality. At one time a blow on the head, insufficient to cause loss of consciousness or bony damage, determined fits; at another, sulphur absorption through the skin. Very possibly some other effective stimulus may be found for him later on. Still, as it stands, the moral of the story is, as Pagniez points out, that where epilepsy does not respond to ordinary methods of treatment, an inquisitorial and exhaustive survey is called for to exclude any possible determining factor.

Dr. Robert Forbes has been appointed secretary of the Medical Defence Union.

AT a meeting of the Royal College of Physicians of London on April 15th, Lord Dawson of Penn was re-elected president.

INSURANCE doctors and chemists regain their standard remuneration on July 1st, when, under Mr. Chamberlain's fourth Budget, the remaining half of the salary cuts of 1931 is restored.

PASSMORE EDWARDS HOSPITAL.—Lord Inverforth has promised £25,000 towards the proposed new building of this hospital which is to cost at least £50,000. The old buildingis very inconvenient, and parts of it are becoming very shaky. The patients received during the past year numbered 1815, which is about the same as in the previous year, and the patients admitted showed a slight decrease.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XLVIII.—PROGNOSIS IN THE SEXUAL NEUROSES

THE difficulty in dealing with this subject is that in the first place there is a certain ambiguity in terminology which makes it necessary to define what we mean by the sexual neuroses; and in the second place there is no one accepted method of treatment for these conditions which enables one easily to assess the results of treatment, and therefore the prognosis. At the same time there is no doubt of the importance of being able to form some judgment on prognosis, since the sexual disorders are, fortunately, in these days being reported to us, as doctors, much more often than they were to our predecessors.

Definition.—It is probable that some would limit rather strictly the number of disorders which could be included under the heading of "sexual neuroses." Prolonged masturbation, impotence, vaginismus, seminal emissions accompanied by anxiety, may be held to be truly neuroses. On the other hand, most medical men, for their own convenience of thought, include under this heading a number of other conditions, notably sexual obsessions, homosexuality, fetichism, sadism, masochism and exhibitionism. In this brief attempt to assess the prognosis, this latter standpoint is taken, and all these conditions, which result either from old emotional conflicts or from warping of the personality in early life, are included. In any consideration of the problem it must be remembered that in fact the sexual neuroses are hardly an entity in themselves. The problem of their prognosis is really that of the psychoneurotic states in general. The majority of these disorders of the sexual life are merely symptomatic of a more general emotional disturbance, and it would almost be a parallel if we were to speak of the prognosis of headache, or any other symptom which may come from one of a number of causes.

Factors affecting prognosis.—There are certain important factors which affect the prognosis in these conditions: age, duration of the symptoms, intelligence of the patient, the degree of desire for cure or for change which the patient experiences, and his social situation, must all be borne in mind as influencing the course of his illness. The severity of the coincident psychoneurotic symptoms may also play an important part in affecting the chances of a recovery under treatment.

The patient who has a philosophy of life, or an ideal which makes him wish for cure, has certainly an advantage over his more hedonistic fellow. It is well known that the homosexual patient, for example, often has no wish to be other than he is, and consequently is never likely to be so. The results of the psychotherapeutic treatment of sexual offenders who are referred from the courts are often very much more disappointing than they are in similar persons who have come of their own free will. It is nowadays a truism to say that all punishment should be treatment, but the converse also holds and occasionally treatment will be regarded as a part of punishment, and therefore resented. Environmental factors will influence the prognosis perhaps more than in any physical disorder. Social conditions are inevitably linked with all these problems of sex. As an example, it is clear that the man who suffers from impotence will find the task of readjustment much more difficult if his wife is unsympathetic or very demanding or querulous. Those who have worked with homosexual patients under ordinary consulting room or hospital conditions, and have also worked with those who are in the process of serving a sentence in prison, will realise that there is a very considerable difference produced by the conditions of prison life and by the general attitude that is likely to be adopted there towards the patient's neurosis.

In the process of weighing up the different factors which affect prognosis one must not be unduly influenced by any one. An intelligent person of 70 who has had a neurosis with a sexual basis for, say, 20 years may get perfectly well. Homosexuality of very long standing may be cleared up sometimes almost as quickly as this condition in the callow, immature youth. Our preliminary judgment on the matter of prognosis, therefore, is only to be arrived at by taking all of the factors into consideration.

TWO GROUPS

It is possible for prognostic purposes to divide the various conditions roughly into two groups. In the *first group* the conditions are, on the whole, less serious and more susceptible of cure by comparatively simple treatment. In this group I would put masturbation, emotional (non-active) homosexuality, many cases of vaginismus, all cases of psychological impotence, mild obsessional states and conditions of seminal emissions with anxiety. All of these are conditions of which, as a rule, the patient wishes to be rid. Few of the patients will need any very serious course of deep analysis, and in all of them one may say that the prognosis is very good provided that the conditions are treated as psychological problems.

Into the *second group* I would put conditions such as active homosexuality; fetichisms (where the sexual impulse has been transferred to some object which is normally non-sexual); transvestitism (the wearing of clothes of the opposite sex); masochism (the achievement of sexual gratification through self-abasement), its converse sadism, and exhibitionism. In these conditions the prognosis is more doubtful. On the whole the patient is not so anxious to be rid of his symptoms, at any rate he is not prepared to pay the price for such a relief in so far as it means giving up pleasure, excitement, and convenience. All the disorders in this group are very deep-seated and their origins usually have to be sought in conflicts and personality problems of the first years of life. For all of them nothing but reductive mental analysis, of which Freudian psycho-analysis is the best-known technique, will be adequate. Without such treatment the victims are very unlikely to recover. Practically all of the patients in this second group can be *helped* by any one with tolerance, commonsense, and some understanding. Every one of them can be helped and improved by psychotherapy, and it is quite certain that a high proportion of them can be, and are, cured permanently by analytical treatment. No psychotherapist or analyst would, however, be so rash as to give a completely optimistic prognosis without some considerable knowledge of the patient.

There is no available evidence as to the course taken by these illnesses in the past, when certainly there were no psychotherapeutic procedures to apply. Such experience as can be obtained from the observation from time to time of cases which receive no treatment, makes it seem that they are unlikely, on the whole, to right themselves. It is, of course, obvious that some of the simplest conditions like masturbation and simple homosexuality may be "grown out of."

METHODS OF TREATMENT

A change in the general circumstances of the patient which gives him fresh interest and perhaps relieves the strain of his life may, of course, tend towards an alteration for the better in his sexual interests. It is, however, in practically every case an unwise and superficial piece of advice to tell patients to get married or to find other sexual outlets. It is a "hit or miss" method and the failures dwarf the successes. It is also of very little use to give stimulating advice to people to pull themselves together and be normal unless we can tell them how to do it. It can only do harm to create a guilt sense in a patient, or to pour scorn or contempt on him for the particular form of his illness, however antisocial it may be. We as a profession, while well equipped with knowledge of the anatomical and physiological mechanisms of sex, have little knowledge of the functioning of sexuality, save what we acquire for ourselves after graduation. It is just that knowledge and understanding of personality and of psychopathological reactions which can prove effective in dealing with sexual difficulties. Given sufficiently early treatment, which involves insight, knowledge, and tolerance, there is little doubt that the deviations of sexual life could be averted or dealt with before they ever became serious.

Once a sexual neurosis or perversion is established, the prognosis depends mainly on the efficacy of the psychological treatment that is given. Suggestion is a method which is not very radical. It may be of use in a few cases of impotence, or with other recently developed symptoms, but it is unlikely to do anything effective for the more established disorders. Education, or re-education, in matters of the simpler mental mechanisms and on the whole subject of sex is of the greatest value to all these patients. Most of those who seek medical help fall into the first of the two groups suggested above, and are helped mainly by a combination of superficial analysis with re-education. The smaller and more serious group need prolonged, detailed investigation if there is to be any chance of permanent cure.

CONCLUSION

The figures of the follow-up of patients at the Institute of Medical Psychology show that some 69 per cent. of the whole group of psychoneurotics are "greatly improved" or "considerably improved," and remain so. The results in the sexual disorders—i.e., in those conditions where the primary complaint is of some sexual difficulty—show a slightly better figure; about 76 per cent. of them appear to be permanently benefited.

In conclusion, therefore, we are certainly entitled to the belief that prognosis in the majority of the sexual disorders is good, if we exclude mental defectives, and if suitable treatment is available. We are certainly justified in encouraging such patients in the belief that, with help, they can achieve freedom from their symptoms and normality in their sexual life.

MINOR EPIDEMICS OF "INFLUENZA"

(EPIDEMIC CATARRH)

A CLINICAL STUDY OF NINE SEASONS, 1924–33

BY G. M. WAUCHOPE, M.D., M.R.C.P. Lond.
ASSISTANT PHYSICIAN TO THE NEW SUSSEX HOSPITAL, BRIGHTON

(*Concluded from p. 881*)

Character of Individual Epidemics

IN considering each year's epidemic as an entity, one recognises that each had its special character or variation. They fall conveniently into three groups :—

(1) Mild.—1925–26, 1927–28, 1929–30.
(2) Moderate.—1928–29, 1930–31, 1931–32.
(3) Severe.—1924–25, 1926–27, 1932–33.

This grouping corresponds partially with the European epidemics given by D. and R. Thomson.[5] Thus 1926–27 and 1928–29 were the most severe generally. The former was the worst of all the local outbreaks, but the latter was in the moderate group. In the locally mild years there were no general epidemics.

MILD EPIDEMICS
(1925–26, 1927–28, 1929–30)

The first group (mild) comprises 63 cases. Reference to the charts of incidence show that in these years the cases were few in number in addition to being mild in character, yet infection spread quickly among members of a household. Disability was of short duration, 80 per cent. of the patients were well in under a fortnight; only 4, who had complications, were ill for more than three weeks. The illness differed in each year of the group.

1925–26 was characterised by nasal catarrh with persistent intractable cough; headache and pains in the limbs were common; in addition to a few cases with definite alimentary symptoms intense nausea was a troublesome symptom.

In 1927–28 sore-throat was the main distinguishing symptom, and although fever was high, recovery was rapid. There were no non-respiratory cases.

In 1929–30 cold in the head and pains in the limbs were part of a very mild illness but it was associated with a rather larger proportion than usual of cases of slight bronchitis.

EPIDEMICS OF MODERATE SEVERITY
(1928–29, 1930–31, 1931–32)

There were 267 cases in this second group. As the charts of incidence show, the illness was fairly extensive, spreading over several weeks. As a whole it was respiratory and of short duration. 47 per cent. of the patients recovered in a week and 34 per cent. in a fortnight. A few cases in each year lingered on into months. Otitis media was the outstanding complication; 23 of the total 35 cases occurred in the three years forming the group, and each year had more cases than any other single year. Other complications were few, except for 35 cases of bronchitis; influenzal cardiac debility occurred in three cases, two in 1928–29 and one in 1930–31; there was one case of rheumatic carditis after tonsillitis on the tenth day of influenza and one of pneumonia in 1930–31.

Each year had its distinguishing character.

1928–29 was the most severe of the three and the incidence reached a sharp peak in the last week of February

(Chart V.). The symptoms were: intense nasal catarrh with streaming eyes and nose, paroxysmal sneezing, epistaxis, noises in the ears, deafness, and shivering. Cough was hard and racking but of short duration. In 9 cases the signs of respiratory catarrh did not appear till the third or fourth day; the patients were first ill with headache and fever, coated tongue, and nausea; one had epistaxis, one epigastric pain, and two pains in the limbs.

1930–31 was the only year in which afebrile cases occurred; neuromuscular pains were frequent and giddiness was a characteristic symptom. Both the respiratory symptoms and the otitis media were milder than in the previous year.

1931–32 was characterised by a comparatively large number of gastro-intestinal cases; 11·5 per cent. were purely alimentary and 31 per cent. in all had gastrointestinal symptoms; the sickness and diarrhœa were unusually violent. Three patients suffered from prostration and post-influenzal debility which did not occur in any other year of the group.

SEVERE EPIDEMICS

The third group (252 cases) was characterised by a high peak of incidence, severe and dangerous complications and prolonged disability. Ten patients were laid up for over three months as compared with two in the moderate group, whilst 30 were ill between one and three months, compared with 11 in the moderate group. The dangerous complications were first, the so-called toxic myocarditis—10 of the total 14 cases occurred in this group and 7 in one year (1924–25); and secondly, pneumonia, 5 cases with 2 deaths. Bronchitis (24 cases) and otitis media (12 cases) were less frequent than in the moderate group and not more severe. Even in these years, however, the majority of cases were of the usual respiratory type; 37 per cent. of the patients recovered in a week and 30·6 per cent. in a fortnight.

1924–25

This year has been included under Group III. because the heart was affected in 9 per cent. of the cases and the average duration of the illness was greater than in any other year. The chart of incidence (Chart I.) does not show a sharp "peak" but rather a broad "mountain" resembling the moderate years. The cold in the head was extremely severe with paroxysmal sneezing and was associated with sore-throat or gastro-intestinal symptoms in many cases; cough was troublesome but "looser" than the typical influenza cough. Delay in the onset of catarrhal symptoms occurred as in 1928–29 and chiefly in the worst cases. Neuromuscular symptoms were common and prostration was marked, either at the beginning of the illness or in later stages, and the year is particularly remembered for the severe cardiac debility which supervened in certain cases.

1926–27

This was by far the worst epidemic of the series both in the severity of the symptoms and the sudden rise in the number of cases within a short period at the end of January. In fourteen households more than one person was affected accounting for 41 of the 86 cases, or nearly 50 per cent. The character of the illness seemed worse in houses where there were several cases; for instance, four children in one family had high fever and two had otitis media with perforation of the drum; another family of four children were severely ill, one had otitis media, and another consolidation of the apex of one lung; and in a household where five were attacked, two had pneumonia, and one of these died; two others were laid up for long periods and only one had an uncomplicated attack. This was the only epidemic in the series during which doctors kept the latch-keys of the patients' houses, there being no one to let them in.

In 71 (82 per cent.) cases the respiratory tract was the main site of infection, and although the cold in the head, &c., was not so severe as in other epidemics, the general condition was worse. A larger proportion than usual (11, or 12·8 per cent.) were cases of "pure" neuromuscular type, and these were the patients who were the most severely ill and in whom the serious complications such as pneumonia supervened.

Prostration was the feature that distinguished this epidemic from the others in the series; it was very severe in 11 of the non-respiratory cases and in an equal number, but smaller percentage, of the respiratory cases (83 per cent. and 15 per cent. respectively). Delirium occurred in 7 of the uncomplicated cases. This was unusual in the other epidemics and is another sign of a more severe disturbance. The temperature was higher and more prolonged than in the other epidemics. The length of time taken to recover and the two deaths emphasise further the serious nature of the illness. The deaths were both due to influenzal pneumonia, which occurred in three cases. These have already been briefly described.

1932–33

This epidemic was second in severity to that of 1926–27; prostration was marked, recovery was delayed, and two patients died. Chart IX. shows that although the number of cases recorded was almost the same as in the previous "moderate" year, there was a "peak" of incidence in the last week in January in 1933, whereas in 1931–32 the main incidence was spread over several weeks.

The symptoms were chiefly respiratory but were associated in 25 cases with headache and pain in the limbs and in 7 with nausea and vomiting. Two patients complained of pains in the bones of the face, nose, and forehead. Prostration occurred in 19 of the more severe cases, but in contrast to 1927 not especially in the non-respiratory type. The character also was rather different from the prostration of 1926–27 where the patients looked poisoned; in 1933 they appeared to be deprived of vitality for no obvious cause; they felt as though they were dying and could hardly be persuaded that there were no physical grounds for so gloomy an outlook. For example, a woman of 56 lay for weeks with a systolic blood pressure varying between 90 and 100 mm. Hg, and a pulse-rate of 100 per minute. She experienced intense nausea and depression, and it seemed almost a hopeless task to instil even a wish to live.

In this year, alone of the series, all the common complications occurred in a few cases. The two deaths were not exclusively the result of influenza. The first patient, aged 70, was dying of obstructive jaundice and, contracting influenza from others in the house, quickly developed a fatal bronchitis; the other was a woman of 60 who nursed other patients and was over-tired. On Feb. 17th a cold in the head began; on the 19th she had a shivering attack after being out in the rain. The temperature rose to 103° F. with a streaming cold and diarrhœa; she was desperately ill with all the appearance of septicæmia when first seen on the 21st; she had a septic corn on the right foot and developed a red, shiny swelling on the right foot and hand. She died on the seventh day, the temperature reaching 106° F. before death. As no blood culture was made it is not possible to know how far septicæmia from the right foot was responsible for death; but certainly the onset was influenzal.

Discussion

In reviewing the nine epidemics here described, several questions arise.

(1) *Was the illness influenza?*—While there is no agreement as to the relation between pandemic influenza and the "influenza" of inter-pandemic years,[5] it may be noted that although the symptoms are very much the same in both the great and the lesser epidemics, the former are seen only once in a generation and the latter almost annually. One possible explanation of this is that influenza vera (pandemic influenza) confers immunity; and the age-incidence in the last pandemics supports this, for in 1889–90 middle-aged and old people were attacked, while in 1918 those who had passed through the earlier epidemic escaped, but the young were decimated. In this respect influenza vera conforms with the known virus diseases, all of which confer permanent immunity (for example, acute poliomyelitis).

The "influenza" in the present series, on the other hand, conferred only temporary immunity. Reference to the charts of incidence shows that relatively severe epidemics occurred only in alternate years, and that in the intervening years there were very few cases; 1931–32 was an exception. In individual cases an attack seemed to render the patient more susceptible. (See under "Length of Illness.")

Therefore, although the similarity of the symptomatology supports the view that the annual or biennial epidemics are milder forms of the great pandemics and present individual cases which cannot be distinguished —for example, even the toxic cases of 1918 were imitated in 1927—yet the evidence of immunity seems to separate them. The question awaits bacteriological proof, and the symbiotic theory emphasised by D. and R. Thomson [5] offers a promising solution, viz., that pandemic influenza is a virus disease [5] and that there may be a heavy infection with *B. influenzæ*, pneumococci, or streptococci at the very beginning of the disease—i.e., too soon to be regarded as a secondary infection; that the bacteria and the virus increase each other's virulence causing severe pandemic influenza; that the concomitant bacteria are pathogenic and may cause primary infections of the respiratory tract without the aid of the virus" (inter-pandemic influenza). They point out that the bacterial infections are more common in the winter, and that the first wave of the 1918 epidemic occurred in the summer and was mild; the second wave came in October–November when the bacterial respiratory diseases were beginning and had a great mortality, the inference being that the first wave was a pure virus influenza, and the second wave due to symbiotic virus and bacterial infection.

(2) *Were the nine epidemics all the same illness?*—They had certain characters in common. For example, the sudden onset, the fever, the catarrhal symptoms, and the comparatively short duration; certainly the respiratory type of illness which was the foundation and background of each epidemic was much the same every year, though differences were found in the severity of the symptoms and the part of the respiratory tract which was chiefly affected, the nasal passages, the throat, and the trachea bearing the brunt in turn. And yet each year's illness had its distinguishing characteristic, so that even when patients had several attacks their illness followed the prevailing type and was not peculiar to the individual as a cold in the head usually is.

The differences were made more conspicuous by the non-respiratory cases, by the presence or absence of prostration, and by the nature of the complications.

(3) This leads to a third question: *Are the alimentary and neuromuscular forms due to the same infection as the respiratory type?*

(*a*) It is often denied by surgeons and consulting physicians that "gastric influenza" exists; they believe that the cases so diagnosed are really appendicitis or cholecystitis. But most of those who have observed epidemics of influenza recognise it.[5] and in the present series both respiratory and alimentary cases were seen in one household while individual cases combined respiratory catarrh with gastro-enteritis; and further, it is hardly to be supposed that in one practice 27 cases of appendicitis or cholecystitis occurred and subsided spontaneously in the course of a few weeks (1931–32). (*b*) The neuromuscular type is not so suspect because aching head and limbs are recognised as part of "influenza" and it is not difficult to accept a form of the illness in which they occur without respiratory catarrh.

It is almost impossible to draw a line between any of the respiratory epidemics and to say that one was and another was not "influenza," and if the identity of the respiratory type is accepted there are two possible answers to question (3).

(i) The respiratory tract, comprising the nose, pharynx, trachea, and bronchi, is the normal site, the severity and actual point of attack being variable; the gastro-intestinal tract and neuromuscular system are also vulnerable, though in a lesser degree by the same virus. The illness in all the epidemics is therefore the same and the non-respiratory forms are variations.

(ii) The non-respiratory type of illness is determined by a secondary or symbiotic infection, and is a complication of "influenza."

The first is the more probable on clinical grounds.

(4) The fourth question concerns complications and may be thus stated: *Which of the concomitants of respiratory influenza are true complications?*

Bronchitis occurred every year and was probably an extension of the "influenzal" respiratory infection, but pneumonia and otitis media only in certain years. Glover [3] points out that these two complications are secondary epidemics and may or may not occur. They are almost certainly due to a supervening or symbiotic infection. Cardiac debility, on the other hand, appears to be a consequence of the influenza alone, and may be a true "variation" like the gastro-intestinal and neuromuscular manifestations, or may bear the same kind of relation as diphtheritic cardiac toxæmia bears to the Klebs-Löffler infection. It certainly occurs in the more severe epidemics and in patients who appear "toxic." Prostration usually appears earlier in the course of the illness than recognisable cardiac weakness. Sometimes it marks the actual onset. The only explanation seems to be an overwhelming toxæmia.

To sum up the position, so far as it can be ascertained on clinical grounds alone, the complications, or supervening secondary lesions, occurring in these epidemics were (*a*) pneumonia, "toxic" or streptococcal and lobar; (*b*) otitis media; and (*c*) the sporadic complications already enumerated. Bronchitis was an extension of the original infection and was similar to gastro-enteritis and the neuromuscular manifestations. Cardiac debility and prostration were either extensions of the original infection to the heart and nervous system—and it is to be noted that prostration was more common to the neuromuscular cases—or were due to "toxæmia."

TREATMENT

No mention has been made of treatment, because the object of this study has been to depict the character of the illness as it occurred from year to year; the treatment was symptomatic and certainly did not influence the type of the illness; it is doubtful if it altered the course and the complications. Mixed vaccines from pneumonic sputum were given in large doses to a few patients in 1927 but only in the worst cases, and there were not enough controls to assess their value.

Prophylactic vaccines have been given to many patients with satisfactory results, but in so far as they were effective in preventing influenza the cases are necessarily excluded from this survey, and there is no evidence that the illness was modified.

Summary

Nine minor epidemics of "influenza" have been described and illustrated by charts of incidence. Clinically the illness occurred in three forms—respiratory, alimentary, and neuromuscular. It has

been shown that in these epidemics, although the main type was respiratory and was more or less similar from year to year, each season's illness showed individual variations in incidence, severity, complications, and in aberrant types. The relation of these catarrhal epidemics to true influenza has been discussed and the ætiology of variations and complications.

It is a pleasure to thank Dr. Robert Hutchison for his helpful criticism.

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

HEALTH INSURANCE AGAIN

A SPECIAL session of the house of delegates of the American Medical Association, called at the request of the board of trustees, met in Chicago on Feb. 15th and 16th and passed this resolution:

> The house of delegates of the American Medical Association reaffirms its opposition to all forms of compulsory sickness insurance whether administered by the federal government, the governments of individual States or any individual industry, community, or similar body. It reaffirms also its encouragement of local medical organisations to establish plans for the provision of adequate medical service for all the people, adjusted to present economic conditions, by voluntary budgeting to meet the costs of illness.

Concerning which the *Survey* remarks that beneath the rather heated language there lies a shift that is rather surprising. "The Association's stand," they add, "for voluntary 'budgeting' plans under the direction of local medical organisations strongly resembles recommendations of the Committee on the Costs of Medical Care which the Association dubbed socialism and communism when they were made a little more than two years ago."

Since the meeting of the house of delegates the important State medical society of California, at a meeting of its house of delegates on March 3rd, has adopted a resolution frankly favouring the compulsory health insurance. It recommends legislation "to establish a health insurance system, mandatory as to certain population groups and voluntary as to certain population groups, which shall include the following principles: (1) The patient shall have absolutely free choice of physician and hospital. (2) The medical profession shall determine the scope, extent, standards, quality, compensation paid for, and all other matters and things related to, the medical and medical auxiliary services rendered under the system. (3) There shall be no provision for cash benefits. (4) The patient shall receive adequate treatment and his physician shall receive adequate compensation."

RURAL PUBLIC HEALTH SERVICE

A very large part of the rural population in this country has never enjoyed the advantage of public health service by full-time (even though untrained) health officers. For years the effort of the Foundations and the U.S. Public Health Service has been to persuade county administrations to employ a "full-time unit"—i.e., at least one public health officer and one public health nurse. The depression has naturally arrested progress in this direction. A compromise with this ideal appeared when certain States began to encourage the formation of districts by legislation permitting two or more counties to pool their resources for the employment of full-time health officers. Two such districts have just been opened in Michigan, each of them comprising three counties. Michigan will now have 38 out of its 83 counties under full-time service. The Ellis Health Law adopted by Georgia a year or so ago makes provision for this same type of district administration. But in both of these States the provision for districts is permissive and not mandatory. The New Mexico legislature of 1935 has gone a step farther in dividing the entire State into 10 health districts and providing that each shall be under the supervision of a full-time health officer. At the same time they have amended the former law so that a levy of one mill (one dollar in each 1000 dollars of assessed property value) is made mandatory in each of the 31 counties and the proceeds go into the county health fund which can only be expended on vouchers signed by the district health officer. Each county will thus have at least one full-time public health nurse, and if some federal aid is granted on the basis of the Security Bill now pending in Congress, each county will have a clerk and a sanitarian (sanitary inspector) as well. The new law has the effect of removing local health work from the domain of political patronage and creates conditions which will encourage health officers to take post-graduate study in public health as an opening to a career.

MATERNAL MORTALITY

In spite of repeated unfavourable comparisons between the maternal mortality of this country and European States, and in spite of various local studies which show that a large number of maternal deaths are preventable, there have always been those who took comfort in the argument that maternal mortality-rates as between one nation and another are not comparable. American statistical practice, it was argued, attributed to "puerperal causes" a number of deaths which in other countries are differently assigned. The complacency of these medical patriots will be rudely shaken by a study made by Dr. Elizabeth Tandy,[1] which has already received some notice in your columns (March 30th, p. 758). Duplicates of 1073 actual death certificates obtained from the U.S. Census Bureau were furnished to 16 countries abroad, and the proper statistical officers classified them according to the procedure in force in each country. The methods of assignment in Australia, Netherlands, New Zealand, and Scotland are similar to our own: their rates are comparable with ours. Under the procedure of Denmark our rates would be significantly higher than those published. Under the procedures of Canada, Chili, Czechoslovakia, England and Wales, Estonia, France, Irish Free State, Italy, Northern Ireland, Norway, and Sweden, the rates of the U.S.A. would be somewhat lower. But it is found that the difference is small, and our relative position remains high under all circumstances.

---

[1] Tandy, Elizabeth C.: Comparability of Maternal Mortality Rates in the United States and Certain Foreign Countries: a Study of the Effects of Variations in Assignment Procedures, Definitions of Live Births, and Completeness of Birth Registration. Government Printing Office, Washington D.C. Pp. 24. 5 cents.

Even if the method assigning the smallest number of deaths to puerperal causes is applied to our death certificates the United States rates would still exceed those of all countries except Australia, Canada, Chili, and Scotland. It is now indisputable that "the United States retains an exceedingly high rate as compared with other countries."

PARIS

(FROM OUR OWN CORRESPONDENT)

UNDULANT FEVER IN FRANCE

SOME years ago Prof. Nicolle described undulant fever as a disease of the future. It was not recognised in France until 1909, but by the autumn of 1932, when the Mediterranean Hygiene Congress was held in Marseilles, an official circular put the annual total at the imposing figure of 3000 cases. Next June the brucellar infections are to have a congress all to themselves—the Premier Congrès des Brucelloses—at Avignon.

There seems to be no doubt that undulant fever is spreading, in more senses than one. Geographically, it has now extended from the Mediterranean littoral up the Rhone and to the Pyrenees and Alps. And not only are the numbers of human and animal cases growing in the infected areas, but cattle as well as goats and sheep are becoming reservoirs of the disease. In 1930 a research centre was established at Montpellier on the initiative of the Bertrand Bouisson Institute and the Rockefeller Foundation, and according to a report on its activities by Dr. R. M. Taylor, Dr. M. Lisbonne, and Dr. L. F. Vidal, in the February number of the *Mouvement Sanitaire*, it should be possible to reduce the number of human cases in which infection is due to the consumption of milk and its products and not to contact with infected animals. The boiling or pasteurisation of milk, before it is consumed as such or converted into cheese, is most certainly desirable and should not prove difficult, but the problem of protecting human beings in contact with infected animals is much less easy to solve. In theory, careful washing and disinfection of the hands after every dangerous contact should prove effective, but at the present time the unsanitary condition under which human beings and animals live together in the south of France are very discouraging to the public health reformer. As for the action of vaccines hitherto prepared, the experience of the Montpellier centre with regard to both human beings and animals is not particularly promising, the immunity acquired by vaccination having so far proved comparatively feeble. It is, however, recommended that the vaccination of human beings be continued among rural populations which are less exposed to massive infections than are the laboratory workers whose reaction to such vaccination has been studied at Montpellier. The ideal solution would, of course, be vaccination of animals which protected them against not only abortion, but also infection. No reliable vaccine for this purpose has yet been prepared; the employment of such living vaccines for cattle is not without its dangers, and the authors have observed two cases of undulant fever due to *Br. abortus*, the source of which can almost certainly be traced to the handling of a vaccine destined for cattle. The alternative of a sanitary cordon around the areas already infected should be feasible. As far as the health of human beings is concerned, it is infection with *Br. melitensis* which must be combated by measures destined to keep the disease within its present geographical limits.

BUDAPEST

(FROM OUR OWN CORRESPONDENT)

A MEDICAL CONSTITUTION

THE long disputes over the regulation of the medical profession have entered a new phase with a Bill now before the National Assembly. On a regional basis the profession will be divided into chambers having between 100 and 1000 members: there will be three in Budapest. Among other things these chambers are to regulate the minimum fees for medical work and establish benevolent funds. Each will send on two members to the national medical chamber which will make regulations about professional discipline and ethics and will also found various welfare institutions. The disciplinary offences include negligence, unprofessional conduct—that is to say, violation of the authority of the medical order or vocation by unsuitable behaviour or an anti-national attitude—and failure to pay fees to the chamber for two years. The punishments include reprimand, fines of 10 to 1000 pengős (12*s.* to £60), and temporary or permanent suspension from practice. A doctor may also be suspended from practice if an action is brought against him in a criminal court.

The Hungarian medical profession in general has received the news of its new constitution with cool indifference, though a group are protesting because they consider that the disciplinary rules are too severe and the advantages offered meagre. They particularly object to the rule suspending a doctor against whom a criminal case is pending, for he may well prove to be innocent. They also consider that in the present plight of the medical profession, in which, as I related in your issue of March 30th, at least a third of our private practitioners cannot earn even a very modest livelihood, it is not fair that non-payment of chamber fees for two years should lead to cancellation of membership—which is equivalent to removal from the medical register.

ADVERTISEMENT OF PHARMACEUTICAL PREPARATIONS

According to the new Bill drugs and chemicals which are included on the list of official drugs, and which must therefore be included in the stock of every pharmacist, even those in the most remote villages, may not be advertised in lay journals, on posters, or in leaflets which are distributed to the public, but they may be freely advertised in professional journals. Articles describing the use of new drugs and new methods may not be published, and interviews to the lay press on drugs which are still being used experimentally should not be granted. A new preparation may be described once, on its introduction, and then only by a medical man in a professional journal. Where a discovery is very important, however, it is permissible for directors of reputable clinics to make statements to the lay press in general terms and with the object of correcting erroneous or sensational inferences. In these circumstances names must not be mentioned.

A DERMATOLOGICAL CONGRESS

Though it is to be regretted that the present financial depression has not yet permitted the formation of an international dermatological association, the delay will make more memorable the ninth international congress which is being held in Budapest from Sept. 10th to 21st. Renewed efforts are to be made at it to form an association, and a number of important committees are meeting to consider technical, administrative, social, and professional aspects of dermatology on the two days preceding the scientific meeting. They will discuss the reform of dermatological terminology (chairman, Prof. J. H. Rille of Leipzig); the classification of skin diseases (chairman, Prof. Howard Fox of New York); the teaching of dermatology (chairman, Prof. H. Gougerot of Paris); the foundation of an international dermato-venelogical scientific exchange centre (chairman Dr. Tomnasi of Palermo); and dermato-venereological medical practice (chairman, Sir Ernest Graham-Little of London). On these subjects they will submit reports and proposals to the final session of the Congress. The official languages of the congress are English, French, Italian, and German, and the English secretary is Dr. A. M. H. Gray, 69, Harley-street, London, W.1.

AN ACCIDENT WITH THALLIUM

A terrible example of inaccurate prescription-writing has lately been before us. A professor in the agricultural high school in Czegléd consulted Dr. X., a lecturer in the University of Budapest, for a fungoid scalp disease of his nine-year-old twin sons. Dr. X. prescribed thallium acetate to bring about depilation, but instead of 0·5 g. he wrote 5·0 g., with the signature: "To the hands of the physician." The pharmacist saw that the prescribed dose was far above the maximum but assumed from the signature that the remedy (which was new to him) would be used externally. Accordingly he put up the powder, as prescribed by the Hungarian pharmaceutical law, in a hexagonal bottle; that meant that it was intended only for external use. Dr. X. himself administered the drug to the children and they both died, after sufferings lasting five days. The police demanded an autopsy and this revealed that the cause of death was overdose of thallium. Although this drug is not official yet in Hungary, it nevertheless appears in the new list and its maximum dose is given as 8 mg. per kg. of body-weight. As the children weighed 30 kg., each should have been given 24 cg.—that is to say, about 0·5 g. was required for the two. Dr. X. had previously administered thallium successfully in 344 cases, but that did not save him from disastrous error.

GRANTHAM HOSPITAL.—The new extension has been finished and the patients and staff have moved in. The old building is now being modernised, and when the work is finished the institution will have 100 beds. The official opening is to be in June.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Forthcoming courses include dermatology at St. John's Hospital, Leicester-square (April 29th to June 2nd); medicine, surgery, and gynæcology at Royal Waterloo Hospital (April 29th to May 11th); thoracic surgery at the Brompton Hospital (May 13th to 18th); chest diseases at the Brompton Hospital (two afternoons weekly, from 5 to 6.30, in June); chest and heart diseases at the Victoria Park Hospital (two afternoons weekly, 6 to 7.30, during June); clinical and pathological course at the National Temperance Hospital (Tuesdays and Thursdays, June 11th to 27th) 8 P.M.); week-end courses will be given as follows: cardiology at the Victoria Park Hospital (May 4th and 5th); chest diseases at the Brompton Hospital (May 11th and 12th); fevers at the Park Hospital, Hither Green (June 15th and 16th); obstetrics at the City of London Maternity Hospital (May 25th and 26th). A supper dance and cabaret is being arranged to take place at Claridge's on Wednesday, June 5th, at 9.30. Courses of instruction arranged by the fellowship are open only to members and associates, with the exception of the dermatology course. The secretary of the fellowship may be addressed at 1, Wimpole-street, W. 1.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. O. D. Brownfield, O.B.E., to *President* for Royal Tournament.

Surg. Comdr. F. C. Hunot placed on the Retd. List, at own request, with rank of Surg. Capt.

Surg. Lt.-Comdrs. H. J. McCann to *Curacoa*, and H. G. Wells to R.N.B., Portsmouth.

Surg. Lt. G. D. Wedd to *Dauntless*.

Surg. Capt. R. C. Munday, C.B., R.N., retired, has been awarded the Greenwich Hospital pension of £50 a year in the vacancy created by the death of Surg. Capt. H. E. South, R.N., retd., on March 10th.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdr. W. H. Butcher to R.N. Hospital, Chatham.

Surg. Lt. G. M. Tanner, promoted to Surg. Lt.-Comdr.

Surg. Lts. D. W. Bawtree to *Iron Duke*; and C. Seeley to *Pembroke* for R.N. Hospital, Chatham.

Proby. Surg. Lt. P. G. Burgess to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS

Capt. J. T. Robinson, M.D., R.A.M.C., is granted the local rank of Maj. whilst employed with the Trans-Jordan Frontier Force. (*Vide* THE LANCET, March 23rd, p. 704.)

REGULAR ARMY RESERVE OF OFFICERS

The undermentioned, having attained the age limit of liability to recall, cease to belong to the Res. of Off.:—

Col. E. L. Moss, C.M.G., M.C. (late R.A.M.C.).

Lt.-Col. M. Keane, O.B.E., R.A.M.C.

TERRITORIAL ARMY RESERVE OF OFFICERS

Capt. R. A. M. Scott, from Active List, to be Capt.

ROYAL AIR FORCE

Group Capt. H. A. Hewat to Headquarters, R.A.F., Halton, for duty as Principal Medical Officer, vice Group Capt. F. C. Cowtan.

Squadron Leaders G. H. H. Maxwell to No. 5 Flying Training School, Sealand, for duty as Medical Officer, and V. R. Smith to Headquarters, Inland Area, Stanmore, for duty as Deputy Principal Medical Officer.

Flight Lts. H. Penman and F. I. G. Tweedie to No. 1 Flying Training School, Leuchars.

Flying Offrs. C. A. Lewis to No. 2 Flying Training School, Digby; W. G. S. Roberts to No. 6 Flying Training School, Netheravon; A. W. Smith to No. 3 Flying Training School, Grantham; G. H. Stuart to Central Flying School, Wittering; J. S. Wilson to No. 5 Flying Training School, Sealand.

Dental Branch.—Wing-Comdr. C. L. Colbran, O.B.E., is promoted to the rank of Group Capt.

RESERVE OF AIR FORCE OFFICERS
SPECIAL RESERVE

Flying Offr. J. L. Howland Easton is promoted to the rank of Flight Lt.

INDIAN MEDICAL SERVICE

Lt.-Col. G. L. Duncan retires.

DEATHS IN THE SERVICES.

Lt.-Col. William Hooper Pinches, R.A.M.C. (retd.), who died on April 9th in London, at the age of 73, qualified M.R.C.S. Eng. in 1884, and obtained his first commission as a surgeon in the following year. He became a major in 1898, lt-colonel in 1905, and retired in 1906. He served with the Hazara expedition in 1891, receiving a medal with clasp; accompanied the expedition to Dongola in 1896, and received the 4th class Medjidie and the Egyptian medal with clasp. He also served with the Nile Expedition in 1898, and took part in the charge of the 21st Lancers at the Battle of Omdurman that year, being mentioned in despatches. He served in the South African War 1899–1902, and was awarded the Queen's medal and the King's medal, each with two clasps. In 1918 he was employed in the Ministry of National Service.

PARLIAMENTARY INTELLIGENCE

OSTEOPATHS BILL

Select Committee's Inquiry

(Continued from p. 900)

THE Committee's inquiry continued on Friday, April 12th, with Lord AMULREE in the chair.

Withdrawal of the Bill

Mr. THORPE, K.C., principal counsel for the promoters, addressing the Committee said :—

This is the twelfth day of our appearance before your Lordships and I understand that after to-day your Lordships will adjourn for a period. I should be lacking in my duty to my clients and my duty to your Lordships if I did not explain my position. You will remember that on the first day of our proceedings, when I opened the case for the Bill, I indicated the way in which I would ask that the Bill should be considered. I said that there were people called osteopaths who were practising, and that whereas there was no distinction between the qualified and unqualified osteopath it was desirable that a register should be formed and a standard laid down by Parliament as to the qualifications that would entitle a man to be registered, and thereafter Parliament should say what duties those who were registered should be allowed to perform. In the course of the inquiry it became inevitable that a different issue should be presented. That issue, as I understand it, took this form, that it was desirable before such a register was granted that the osteopaths should prove scientific justification for their theory. I think I am quite fair in saying that that was the main point taken by the medical profession. That being so —and I do not think I could have resisted it—we get into this position, that your Lordships were asked to make a finding on a matter which at any rate is beyond some of your Lordships. When I try to find out the merits of this matter I find I am reading a language which I do not understand and that it is completely beyond me. So if we are to wait till your Lordships have decided that matter, we may be here longer than we at present anticipate.

The Bill as originally put forward, or the Bill as now presented by us, requires for its main structure the existence and continuance of the British School of Osteopathy. You will remember that Dr. Macdonald in his evidence said he himself was not satisfied with the standard taught by that school, and as the school now existing forms such a material part of the Bill I do not feel justified, and my clients do not feel justified, in asking your Lordships to pass the Bill with that school as it is at present constituted, occupying that position in the new organisation. That being so my clients say that we should not be justified in asking your Lordships to pass this particular Bill. I would not like to find myself in the position of trying to induce your Lordships to pass something which we believe to be fundamentally unsatisfactory. But I hope that your Lordships will not think that the osteopaths have lost any faith in the theories for which they stand. You will remember that Dr. Macdonald and Mr. Streeter both said publicly that they would welcome any inquiry and that they were prepared to take up any challenge made against them for the purpose of proving their doctrines to be scientifically sound. The position altered considerably, I think, when Sir Norman Walker was before your Lordships and said that he would have no objection to an investigation. [The relevant evidence was quoted; see THE LANCET, April 13th, p. 895.] We also had the evidence of Sir Arthur Robinson, who expressed the considered opinion of His Majesty's Government and stated that it appeared to the Minister of Health that a sufficiently strong case had not been made out for the adoption of the proposals of the Bill at the present time, and that the proper action at present was to set on foot an organised and careful scientific inquiry into the theory and practice of osteopathy by a properly constituted authority. [See THE LANCET, April 13th, p. 897.] This is a policy which I earnestly pray your Lordships will feel disposed to accept. I am instructed to say that immediately a voluntary register of osteopaths will be formed and that as soon as possible a School of Osteopathy qualified in the views of the osteopaths to give a proper training will be constituted and a clinic will be brought into operation. It is not for me to do more than to urge respectfully upon the Committee that an inquiry in the form of a Royal Commission or some equally responsible body should be asked to consider the scientific justification for the theory and practice of osteopathy. That is naturally in the Committee's discretion. May I suggest that the gentlemen who have already expressed their condemnation of osteopathy in the statement which has been placed before your Lordships, qualified though they may be to judge in this matter, would not be the best judges on a question which one hopes and anticipates that such a Commission will approach with an open mind.

Whatever may be the merits of this case I should like in public to make this claim, that the present Bill and the present inquiry have been asked for and promoted by the osteopaths themselves. One of the medical witnesses suggested that their cause was fraudulent. I would like to recall that it was the osteopaths with the assistance of the noble Lord (Viscount Elibank) who have come into the open and urged the presentation of this Bill in Parliament. They have satisfied at any rate one noble Lord, and they are ready to submit with confidence to any issue which has to be decided hereafter by an impartial tribunal. I thought it right to say what I have said at this juncture. It seems to me that the alternative will be the hearing of evidence on behalf of the medical and other professions, directed to an issue which is perhaps not an appropriate issue for your Lordships to consider. As far as this Bill is an issue before your Lordships I am instructed to say that in its present form we do not press it upon your Lordships. I have had an opportunity of speaking to the noble Lord who introduced the Bill in your Lordships' House and I have spoken with his authority.

ATTEMPTS TO CLARIFY THE POSITION

Mr. RADCLIFFE, K.C., counsel for the Royal College of Surgeons of England, the Royal College of Physicians of London, and other objectors to the Bill, said that if the Bill was no longer being promoted there was no longer any scope for him to call further evidence. If some recommendation was being asked for from the Committee in favour of an inquiry or a Royal Commission, he felt bound to state that the further evidence that the Committee would have heard would have been directed towards passing very severe comments on the scientific value of the suggested evidence in the Still Bulletins. If that evidence was not called he hoped that it would not be taken that the very eminent medical gentlemen who would have given evidence considered that there was evidence of any scientific value at all in these Bulletins in favour of osteopathy.

Mr. THORPE said that he was sorry that his learned friend had thought proper to say that. If their lordships decided not to pursue the matter further he took it that there would be no finding at all one way or another on the issue whether osteopathy was founded on a scientific basis or not and that they would part, neither party claiming a victory.

Mr. DICKENS, counsel for the British Medical Association, said that he did not want to depart from the general attitude of amiability in this matter. If Lord Elibank and the other supporters of the Bill were going to withdraw their support from it there was nothing left for their Lordships to consider.

Mr. THORPE : I was not speaking for Lord Elibank.

Mr. DICKENS : I want to know. Surely my clients are entitled to know whether the Bill is to be proceeded with or not.

Decision to hear Two more Witnesses

After the Committee had consulted in private the Chairman announced that having heard the statement of counsel they had decided to hear two more witnesses—Sir Henry Dale and Dr. Graham Hodgson.

In answer to the CHAIRMAN, Mr. THORPE said he did not propose to cross-examine the last witness

(Mr. Souttar), but it was not to be assumed that he accepted his evidence.

Dr. Graham Hodgson Examined

Dr. H. K. Graham Hodgson said that he was an M.R.C.P., held the D.M.R.E. Camb., was examiner in radiology for the Conjoint Board, a university teacher in radiology at the Middlesex Hospital Medical School, and a practising radiologist. He had had an opportunity of examining the radiograms which Dr. Macdonald had produced to the Committee and he had read Dr. Macdonald's evidence. There were three cases described in seven radiograms. All of the radiograms showed curvatures or other abnormalities of the spine. There was, according to his experience, nothing novel in the abnormalities shown. They were the sort of abnormalities which he saw week by week in his practice, and were the kind which orthopædic surgeons constantly treated by orthodox methods.

Counsel: Before this inquiry opened you had heard of osteopathic lesions ?—Yes.

Had you ever been able to discover what exactly was meant by the osteopathic lesion ?—I tried to on every occasion when I came across a case which had gone on to an osteopath after being treated by an orthodox doctor. In most of those cases I endeavoured to find out what exactly the interpretation was that the osteopath put on the film which I had taken, but I could not understand what exactly was meant by an osteopathic lesion until I read Dr. Macdonald's recently issued book "The Scientific Basis of Osteopathy."

Since you have read that book you think you understand what is meant by an osteopathic lesion ?—Yes, I think I do.

CRITICISM OF INTERPRETATION OF RADIOGRAMS

Shown examples of radiograms supplied by Dr. Macdonald, the witness said that there was nothing unusual about them. They were all examples of ordinary curvature of the spine. Referring to a radiogram of the fifth lumbar vertebræ which it had been suggested was a good example of an osteopathic lesion, the witness said that there was nothing wrong with the fifth lumbar vertebræ. It was merely a case of the way the radiogram was taken. A radiologist had to centre over exactly the same spot every time, otherwise the radiograms were not comparable. In one of the two radiograms, which were taken at different periods, the tube was centred at one point and in the other it was centred three inches above that point. Therefore the radiograms were not comparable. One was a bad radiogram and the other was a good one.

The witness added that Dr. Macdonald talked about "the tilting of the pelvis." The pelvis (Dr. Hodgson commented) was tilted because the hip joints were tilted. The inference drawn from the radiograms was thoroughly unsound.

Counsel proceeded to quote from "The Scientific Basis of Osteopathy" as follows :—

> "It is rare that the stereoscopic film fails to show a lesion which is palpable to the fingers. It is true that bony maladjustments are sometimes absent in the film when they are considered to be present by the evidence of the palpating fingers; in such cases the X ray film nearly always shows the localised œdema or fibrosis which is responsible for giving the deceptive findings on palpation."

The witness was asked for his comments on that passage. He said that the radiograms put in to demonstrate these lesions were simple adolescent curvatures of the spine which had been recognised by the medical profession for ages. The ages of the patients were 15, 20, and 23.

EXPERIMENTS TO TEST CLAIMS

On seeing the statement quoted the witness determined to carry out a series of experiments to test the truth of that claim. Since localised œdema was simply waterlogging of the soft tissues of the body as a result of strain or neighbouring inflammation, he decided to make an artificial œdema: he took a piece of steak 1¼ inches thick and cut from it two sections, each weighing 1½ ounces. He then injected into one piece of the steak as much water as he could get into it, using a hypodermic syringe, and increasing its weight by 50 per cent. Both ends of steak were placed in relation to the spine and X rayed, and no difference in density of shadow could be detected. A radiogram of the result was exhibited to the Committee.

It was impossible to detect a small collection of fluid by X rays in this situation, through the whole thickness of the body. Dr. Hodgson described a further experiment in which he took radiograms of his butler's stomach before and after the latter had drunk a pint of beer. The fluid was not visible in the radiogram.

Counsel: As far as you have been able to test it the claim made by Dr. Macdonald is not scientifically accurate ?—I am quite sure it is not accurate.

If it were true it would be of great importance to science ?—It would be a tremendous help. For years experimental work was carried out in order to try to visualise the gall-bladder by finding a dye which we could introduce into the gall-bladder to make it opaque to X rays. A gall-bladder may contain an ounce of bile, but it is quite impossible to X ray it in the ordinary way. In his book Dr. Macdonald says with regard to these cases of œdema that it is only a very small effusion, perhaps a teaspoonful. In an experiment I injected as much as 40 teaspoonfuls of fluid into or alongside the spine of a corpse and could not see it in a radiogram, and he claims to be able to see something like a teaspoonful.

The claim is important in regard to the existence or non-existence of the osteopathic lesion ?—I think it is of fundamental importance.

Did you go into the question of fibrosis ?—Yes. I took a patient who had had seven major abdominal operations. The abdomen was simply covered with scars. I took an X ray and no scars whatever were apparent. Perhaps Dr. Macdonald will tell me where the scars were. I then took quite a thick tendon from the back of the heel, placed it on the abdomen, and X rayed the patient. There was no sign whatever in the radiogram.

Dr. Hodgson added that Dr. Macdonald also pointed to a shadow which he called fibrosis of the lateral ligaments of the spine. That could not be the case because there were no lateral ligaments of the spine. There were anterior and posterior and other ligaments of the spinous processes, but no ligaments on the side of the spine, because it was there that the vessels and nerves came out which Dr. Macdonald talked such a lot about.

In answer to a general question witness said he had never detected, in his experience, which included the examination by X rays of hundreds of cases of abdominal conditions every year, any relation between lesions of the spine and abdominal disease, and could hardly have missed evidence of such a relation if it existed.

Dr Graham Hodgson Cross-examined

Cross-examined by Mr. Thorpe, witness said that the duration of exposure did not affect the results under discussion. From the radiographic point of view an artificial œdema, simulated by massaging the muscles of the back of a corpse into which fluid had been injected would produce just the same effect as œdema in a living person.

INTERPRETATION OF RADIOGRAMS

In answer to Lord Dawson, witness said that it was technically impossible to discern by X rays infiltration of fluids along the soft tissues by the side of the spine.

Asked about interpretation, the witness said that a radiogram could not lie, but the radiologist might misinterpret it.

What occurs to you to be the story told by an X ray photograph may not be the story conveyed to another medical man ?—No, of course not. You may have differences of opinion. But on a condition such as this we are talking about, œdema, there is not one radiologist in this country who would agree with what Dr. Macdonald has said.

Would all the radiologists in England arrive at the same conclusion as you have arrived at from that picture ?—Yes, I am quite certain of that.

Witness criticised Dr. Macdonald's interpretation of a radiogram showing spinal curvature in a patient, and Mr. Thorpe said that it seemed to him fruitless to pursue this cross-examination. Dr. Macdonald did not accept these criticisms of his X ray photographs and he had his answers.

Lord Dawson : May we take it that from the purely radiological and technical point of view the osteopathic lesions (œdema and fibrosis) we read of in this book are incapable of being shown ?—Witness : Alongside the spine, yes.

In answer to Lord Elibank, witness said that he believed he understood what was meant by an osteopathic bony lesion. Dr. Macdonald had quoted Louisa Burns's definition of it as " a disturbance in the relation of bones, not associated with rupture of ligaments, and usually not of a degree beyond the possible normal relations of these under certain circumstances." A curvature of the spine, such as was shown in the radiograms submitted, was, as far as witness understood it, called an osteopathic bony lesion. An osteopathic vertebral lesion was apparently thought to be a lesion of the soft tissues and joints. Dr. Macdonald gave only 1½ pages in his book to the X ray evidence of this type of lesion, though he said that this was the most authoritative evidence on the lesion.

Viscount Esher : Do you consider the radiogram scientifically fool-proof, and that it can be relied upon with absolute certainty ?—Witness : Yes, the radiogram is fool-proof. But it is the interpretation that is the essential thing.

Viscount Esher : We know that doctors often differ and make a different diagnosis from the same radiogram ?—Witness : Not often. I am sure that there is no radiologist on the staff of any hospital in the country who would agree with what Dr. Macdonald has said.

Viscount Esher : You think that your radiographic demonstration proves that there is nothing in the osteopathic theory ?—Witness : I have nothing to do with theory. I am simply concerned with the facts as shown. What Dr. Macdonald has said with regard to œdema and fibrosis is entirely wrong.

Viscount Esher : Is that sufficient to prove that there is nothing in the osteopathic theory ?—Witness : That is for your lordships to judge. I cannot say that. I am simply speaking with regard to the X ray evidence.

In reply to questions by Viscount Elibank, the witness said that it was stated in the book referred to that the osteopathic bony lesion is a disturbance in the relation of bones. Ordinary curvature of the spine would fit into this definition although he would not himself describe it in that way. Medical men saw many cases of that sort every day.

Viscount Elibank : If you accept that, may it not be that the osteopathic method of treating these cases which you see every day is a better form of treatment than that given in the past by medical people ?—If they cannot adduce any more scientific proof than they have done in these X ray photographs I cannot see much chance of that.

In reply to further questions, the witness said he had taken 1500 radiograms of cases of acute pneumonia in the past two years and had noticed nothing wrong with the spine in any case ; nor had he ever seen any connexion between the upper cervical vertebræ and disease of the accessory nasal sinuses.

Sir Henry Dale's Evidence

Sir Henry Dale, F.R.S., director of the National Institute for Medical Research, was next called to give evidence. Examined by Mr. Radcliffe, K.C., he stated that he was an F.R.C.P., a member of the General Medical Council, and secretary of the Royal Society. He had examined, as far as he could in the time available, the Research Bulletins submitted to the Committee, with particular reference to Bulletin No. 2, dealing with experiments of a physiological type. These Bulletins contained some papers which appeared to deal in no sense with the osteopathic theory.

Counsel : What are your conclusions as to the general work shown by the remainder ? Do you think that the evidence they contain is the kind of evidence you would recommend for submission to such a society as the Royal Society for its consideration ?—No. I should not take the responsibility of recommending it.

Or for publication in any scientific journal that you were responsible for ?—I think if I were called upon to give an opinion as to the suitability for publication in any scientific journal of any of these contributions—except one which has no reference to osteopathy and which was properly published in the *American Journal of Physiology*—my opinion would inevitably be that they were not really scientific papers.

That is not because of any doctrine which they tend to support which you do not agree with ?—The Witness : No. My prejudice, if I had any, would be in favour of a doctrine which ran contrary to received opinion. That is inevitable. If one is a scientific investigator, one spends one's life examining the basis of accepted views and hoping that one will be able to enlarge science by upsetting them and substituting sounder views on better evidence.

What would be your objections to recommending these papers as worthy of scientific consideration ?—My difficulty would be that they do not seem to me to have the first qualification of really scientific investigation, which is to obtain new knowledge. They have the appearance to me of being experiments carried out in order to provide what might look like evidence for a theory already accepted. That in itself might be valuable as direct evidence in favour of a theory only supported hitherto by clinical observation. But it would be at that point, I think, that the real scientific investigation would begin—namely, to discover what was the manner of the suggested relation between particular spinal lesions and particular physiological effects. I find no evidence of any attempt to discover the manner of the relation. The object seems simply to find evidence that it exists.

Are you yourself an experienced research worker ?—The Witness : I think that I have had a good experience of research. I have spent all my active life at it.

I suppose that it is necessary for that purpose to be experienced in the phenomena of experiments on animals ?—For the particular kind of investigation with which I am concerned and for the reports with which Bulletin No. 2 deals, yes.

Do these workers show a sufficient knowledge of that in their paper ?—I formed the impression that they do not.

Do they show the ability to distinguish what is important from what is unimportant in research ?—I should say that they do not show that ability.

THE ALLEGED PRODUCTION OF GLYCOSURIA IN DOGS

The witness proceeded to comment on an experiment described in Bulletin No. 2, purporting to demonstrate the production of glycosuria in dogs by artificially created osteopathic spinal lesions. What struck him in the first instance, he said, was that the author of this paper described a number of things which, to the mind of an experienced research worker, appeared like glaring anomalies as though they were matters that could be accepted without comment. The investigator took 33 dogs for the experiment and he subjected them, quite properly, to a period of preliminary observation under the conditions of the experiment. They were caged and fed as they would be after the spinal lesions were created. It was not apparent that any effort had been made to choose the dogs with a view to their special suitability for the experiment. The investigator found that of these 33 animals 18 showed natural glycosuria to such an extent that he could not use them for the experiment. In other words, he appeared to discover in over 50 per cent. of normal dogs a degree of glyc suria of the same order as he expected to produce by the infliction of the spinal lesion on others, and he had to throw out 18 of them before he began.

The second point that struck him, said the witness, was that when the investigator selected his 15 animals—which showed at most what he called a trace of sugar in the urine—for the experiment and proceeded to inflict the spinal lesion and to produce degrees of glycosuria described by Dr. Macdonald in his summary as of various degrees up to as much as 5 per cent.—which was a very high degree—there was no evidence throughout the description that any of these dogs showed symptoms compatible with glycosuria of that degree. Some of them gained in weight. Their appetities were not a matter of comment, except that they remained good; they were not said to be excessive. There was no description of them showing any abnormal hunger or thirst; and, what was particularly striking, was that the volume of urine excreted by these dogs which had been rendered glycosuric by the spinal lesion was, in the majority of cases, smaller than that which they were excreting before the lesion was inflicted.

The witness said that he found it impossible to attach any scientific importance to all this. If the glycosuria described was a genuine phenomenon, then it was something quite new, and having no relation to diabetes in man, for example; and no attempt was made to explain it. It was apparently accepted; and although he did not think that the statement was directly made, the implication was that this was an experimental demonstration of the fact that a spinal lesion could produce glycosuria of the type which was important in human disease.

COUNSEL: Even if it could be shown that spinal manipulation reacted on remote parts of the body, would that of itself be of scientific importance?—I do not think that in itself it would be of scientific importance. I can imagine circumstances in which it might be interesting; but the investigation, the scientific work, would begin with the attempt to trace the nervous channels by which the spinal lesion produced the remote effect.

It is the "How?" and not the fact which is important? —Yes.

Is that an example of what you find throughout the Bulletin, and not an extreme case?—I think so. I have chosen it as what seemed to be an important example, and one on which I believe some reliance has been placed in previous evidence.

Witness said that he found no convincing evidence that would justify the attribution of particular diseases to particular osteopathic lesions, and repeated this in answer to questions with special reference to typhoid fever, diphtheria, epilepsy, and diabetes. The witness commented on another experiment referred to by Dr. Macdonald in his book (p. lxxxvii.). He described the deduction from the results of this experiment that the spinal lesion was a possible ætiological factor in splenomedullary leukæmia was not science—it was simply nonsense. In answer to further questions the witness said that he had found no evidence that pernicious anæmia or asthma could be attributed to particular spinal lesions.

Having studied the work shown in these Bulletins, do you think it is work of a kind which would justify the pecuniary support of the Medical Research Council?—I do not imagine that the Council would be inclined to make a grant in support of work of this kind if it knew this was going to be the kind of result. That is all I can say.

Sir Henry Dale Cross-examined

Mr. THORPE asked whether witness agreed with the opinion expressed by Sir Norman Walker, who had said that he would not mind a proper investigation into the theory and practice of osteopathy, and would go the length of welcoming it.

NO SCIENTIFIC JUSTIFICATION FOR FURTHER INQUIRY

The witness said Sir Norman Walker was concerned with the whole question of the science and practice of osteopathy while witness had been asked for evidence on what was represented as the scientific basis of osteopathy. If asked whether he thought it worth while to hold a public inquiry on the scientific merits of what had been tendered as a scientific basis, he would say that he did not think there was any scientific basis to inquire about. He had no views to express on the point of the practice of osteopathy.

COUNSEL: Sir Arthur Robinson stated that the proper action at present was to set on foot an organised and careful and scientific inquiry into the principles and practice of osteopathy. Would it be correct to assume that the best informed medical opinion is available to the Ministry of Health?

WITNESS: I should think so. The Ministry's statement is a statement as to what they regard as the proper action from the administrative point of view. On that matter I do not care to express any opinion in agreement or disagreement with the Ministry.

The witness said he had studied the Bulletins submitted by the promoters to the extent that time permitted. He could not claim to have read every word. They had been in his hands rather under a week. He had read No. 2 in extenso because it dealt with matters on which he thought his opinion was something of a specialist's opinion.

Are the ignorances or illogical conclusions obvious to a scientific man? Would a scientific man reading Bulletin No. 2 come to the conclusion that there was nothing in it—that it was all rather nonsense?—Speaking as an individual scientific man, that was certainly the impression it made on me. I would not go so far as to say that it was "all rather nonsense." A good deal of it is commonplace and unconvincing. But what appears to me to be nonsense is the implied suggestion that evidence of this kind has any bearing on the claim that the osteopathic lesion is either the determining or predisposing cause in the majority of human diseases.

There are at least five registered medical practitioners who believe in and practise osteopathy. There is no suggestion against their honesty or intelligence, and if they apply the test you apply to Bulletin No. 2, ought they to know at once that the whole thing is unscientific? —May I put it this way. I do not think any medical man who was not previously convinced of the essential truth of the osteopathic doctrine would be convinced of it by studying the evidence presented in Bulletin No. 2. If on other grounds, by practical clinical observation and general experience, he had somehow convinced himself that osteopathy was true, I think he would read Bulletin No. 2 with that in his mind, and he would get the impression that there were a number of statements there compatible with the truth of the doctrine.

Would it be unfair to suggest that a registered medical man who has spent his life in beliefs contrary to osteopathy would approach an investigation with prejudice—not conscious prejudice?—I do not know what a registered medical man would do. I am rather at a disadvantage. I have never been in practice. My life has been spent in research.

Witness said he had not heard a great deal about osteopathy. He had heard it mentioned from time to time in the last 30 years. His investigation into Bulletin No. 2 was the first research work he had considered it desirable to make into the theory of osteopathy.

Re-examined by Mr. RADCLIFFE, on behalf of the Royal Colleges, the witness said that he did not find at all convincing the evidence put forward in support of the theory that the osteopathic lesion caused abnormalities in the alimentary canal.

Lord ESHER asked if a period under a week was sufficient to make a complete examination of the theory of osteopathy. The witness said he thought he had sufficient time to cover the suggested scientific basis for the theory of osteopathy. To make a detailed and critical examination of the evidence put forward in those various Bulletins would take several months, but he should be sorry to spend several months on such a task, because the evidence consisted very largely of repetition of statements on supposed evidence which was entirely unconvincing.

Lord ESHER: You know about the immunity theory of the osteopaths. Their theory is that if your body is in a proper condition you will not be liable to get those diseases ?—WITNESS: That is not only an osteopathic theory; it is a generally accepted medical theory.

The witness said he did not think any responsible medical research institute could undertake an investigation into the allegation that an osteopathic lesion altered the resistance of the body unless there was a reasonable body of prima facie evidence, and not merely evidence of the supposed effect but evidence as to the suggested mechanism. A statement that a cure was the result of the treatment involved an assumption. If the evidence in favour of the assumption justified examination it was worth investigation. But in the case of a new assumption with no apparent rational connexion with known facts of physiology it seemed to him that the onus of providing the evidence in favour of the assumption was on those who put forward the assumption. He suggested that no body of evidence had been produced in favour of the assumption in question to justify the expenditure of valuable time and money on medical investigation of its proof. Lord ELIBANK asked if the witness would have a share in nominating members on the committee of inquiry, assuming the Medical Research Council were asked to set up such a body. The witness replied that supposing the Medical Research Council were asked to set up such a body they might ask his advice.

Lord ELIBANK: If they asked your advice they would ask the advice of one who was prejudiced against osteopathy ?—I am not prejudiced against osteopathy. I have started with a perfectly open mind, but with a prejudice as a scientific man in favour of finding something which goes contrary to current tradition. It would be a disappointment to me not to find any convincing evidence.

In the short time you have not found it worth while to investigate or examine the results of the practice of osteopathy ?—That is outside the particular range of evidence which I have been invited to give to the Committee.

In reply to further questions, the witness said that he had not attempted to criticise the practical results of osteopathic treatment. He had been asked to express an opinion as to the scientific value of the evidence put forward. The examination of patients to be treated by osteopathy would be outside the range of his expert knowledge. He was not a practitioner of medicine.

Lord ELIBANK: In that event you do not disagree with Sir Norman Walker when he says he would be quite in favour of setting up a Royal Commission to investigate the whole principle of the theory and practice of osteopathy ?—I have not expressed any disagreement with Sir Norman Walker on that point. I have only said if a Commission or Committee is to be set up I do not think the evidence tendered on the scientific basis of osteopathy would justify the expenditure of public money and so on, in an investigation of that alone.

You say that without any knowledge of the practice of osteopathy ?—My statement is related simply to the experimental basis. I express no opinion as to the justification or otherwise of setting up a Royal Commission to investigate the practice of osteopathy.

This concluded the evidence of Sir Henry Dale.

Suggestions for Further Evidence

Mr. RADCLIFFE, addressing the Committee, said they had reached the position now when, as he understood it, the Bill was no longer being promoted. If it was merely withdrawn there would be no need for further evidence. But if the position was that some recommendation was still being asked for from the Committee in favour of an inquiry of some sort, or a Royal Commission, then he would have to ask their Lordships to hear relevant evidence.

The CHAIRMAN said the Committee had not considered the matter and they could not express any opinion at present. They would deal with the evidence brought before them.

Mr. RADCLIFFE suggested that the Committee would want to hear further evidence on the question as to whether or not it was proper that any public inquiry should be held.

Mr. THORPE said he thought his learned friend had misunderstood what he had said. The immediate question before their Lordships was their report to the House of Lords, whether the Preamble was proved or not. He was so bold as to ask that their Lordships might be kind enough to consider whether the evidence they had heard would justify them in making any recommendation. His learned friend now asked whether they would make any recommendation. The only issue before their Lordships was the Preamble. It so happened that the Ministry of Health and other witnesses had indicated a certain course. This was before their Lordships and he had asked them to consider it. His learned friend could not call evidence now as to whether the Committee should exercise their discretion in a particular way.

Sir W. JOWITT, on behalf of the British Medical Association, said that if a defendant's case was stopped halfway through by a court it must be and could only be on the assumption that he had won. If his victory was being qualified he had the plain right to call the whole of his evidence. If their Lordships were going to say they wanted to hear no more evidence they knew what that involved.

The CHAIRMAN said they had not stopped any evidence. Mr. Radcliffe had said that in view of Mr. Thorpe's statement he did not propose to call further evidence. The Committee had then decided for their own satisfaction, and for any decision they might come to, to hear two further witnesses.

Mr. RADCLIFFE said that he now understood the Bill could not be withdrawn except in the House of Lords. The Bill was thus before their Lordships and he could not close his case without calling his evidence. Mr. THORPE remarked that if their Lordships reported that the Bill should not proceed, then it was a mere formality.

Their Lordships having consulted in private,

The CHAIRMAN intimated that the Committee did not propose to alter the decision they arrived at in the morning. That concluded the hearing unless counsel wished to address the Committee.

Mr. RADCLIFFE said he was prepared to address the Committee on the Bill at large. If there was a possibility that their Lordships would report favourably on the Bill he must make his speech. Only an intimation from their Lordships that that would not be the case would make him refrain.

The CHAIRMAN: I thought you might draw that inference.

Mr. RADCLIFFE: Your Lordship having said that I think it would not be right for me to say more.

Arguments against Recommendation of Inquiry

Mr. RADCLIFFE added that the promoters of the Bill no longer wished that its provisions in any form should be reported on favourably by the Committee, if he understood the position. If that was the view put forward by the promoters he would ask their Lordships to accept the position and merely report in favour of the Bill not being proceeded with. Whether or not there were other steps that it might be right to take in order to establish the alleged position of osteopathy in this country was a matter which in their Lordships' position it would not be right to go into. It might be that the Minister of Health might think it right to institute or promote some inquiry of his own. That was a matter for his own discretion. He respectfully urged on their Lordships that they should not, in reporting in favour of the Bill not going forward, give any expression in favour of the view that the osteopaths had somehow made out a prima facie case in favour of having the practice and the theory of osteopathy inquired into by this public body. That issue had not been fully canvassed before the Committee, who had heard substantially only one side of the matter. He hoped the Committee would not say anything in their report that would seem to prejudge the case.

Mr. Dickens, on behalf of the British Medical Association, said that the Association would not have closed their case in answer to the Bill had it not been arranged that the scientific witnesses who had not given evidence then were to be called by others. They had examined the evidence for the scientific value of osteopathy which had been put before the Committee by Dr. Macdonald and were prepared to speak as to its value. He accepted the decision of the Committee not to hear any more witnesses but he hoped they would bear these facts in mind.

Mr. Thorpe said he wanted to dissociate himself from Mr. Radcliffe in the suggestion that if their Lordships favoured an inquiry that would mean that the osteopaths had made out a prima facie case. If their Lordships threw out the Bill and made no recommendation, it must follow from that that the osteopaths had proved no case. It would be most unfortunate if any decision of this Committee were to be advertised either as a victory for one part or the other. The matter had not been fully dealt with from a scientific point of view, and their Lordships would not think him disrespectful if he said that they were not the best people to deal with purely scientific questions. Any recommendation their Lordships might think fit to make would be in the public interest and would not reflect on either party or give either of them the right to say that they had won in a dispute.

The proceedings of the Committee then came to an end. A report will be submitted by the Committee to the House of Lords.

NOTES ON CURRENT TOPICS

The Budget: Income-tax Concessions

In the House of Commons on Monday, April 15th, Mr. Chamberlain, Chancellor of the Exchequer, made his Budget statement. In the course of a review of the past year he said that industrial activity had increased by 12 per cent. and manufacturing output had established a new record. Exports were up by £30,000,000. The January registration of motor vehicles was 30 per cent. and the February retail trade 4·9 per cent. greater this year than in the same period of 1934. There had been no rise in the cost of living, and savings of the nation had increased. The true surplus of revenue over expenditure, other than that devoted to debt redemption, was £19,500,000.

The total estimated revenue for the coming year was £735,580,000, and the total estimated expenditure was £729,970,000, leaving a prospective surplus of £5,610,000, which was increased to £11,025,000 by an appropriation from the Road Fund, the yield on the heavy oil duties and minor items. Dealing with changes he proposed to make in his Budget, the right hon. gentleman said that the total taxation now borne by heavy oil vehicles doing moderate annual mileage was only one-half to two-thirds of that charged on corresponding petrol vehicles. The diversion to heavy oil vehicles was involving considerable loss to the revenue, and from August 1st next the differential licence duty imposed in 1933 on heavy oil vehicles would be removed and heavy oil used as fuel by road vehicles would be taxed at the same level as petrol, namely, 8*d.* per gallon.

Mr. Chamberlain explained that the proposals he proposed to make in regard to income-tax allowances involved a change of method for the reasons, among others, that a return to the pre–1931 position would involve withdrawal of the 1931 concession which increased the earned income allowance from one-sixth to one-fifth, and that last year's reduction in the standard rate of income-tax had benefited the larger, rather than the smaller taxpayers. This year the small taxpayer, especially where his income was near the bottom of the scale, was now to have his turn. Instead of the first £175 of taxable income being charged at half-rate (i.e., 2*s.* 3*d.* in the £), the first £135 would be charged at one-third rate (i.e., 1*s.* 6*d.*). Thereby, 2,250,000 (or 70 per cent.) of the taxpayers whose taxable income was below £135 would get relief of 9*d.* in the £—three times the relief which they got last year; and 200,000 whose taxable incomes were between £135 and £175 would get relief in diminishing degree as the taxable income rose to £175. For example, a married man with three children having an earned income of £500 would have his income-tax reduced by the new proposal from £13 10*s.* to £9. It was proposed to increase the personal allowance for married taxpayers from £150 to £170.

With regard to the children's allowances, the right hon. gentleman said that these at present stood at £50 for the first child and £40 for each subsequent child. He looked on the continued diminution of the birth-rate in this country with considerable apprehension. At the present time it might seem that we had here a larger population than we were able to support in England. At the same time, they knew the difficulty which the Dominions found in accommodating a larger population when they themselves were troubled with unemployment. He had a feeling that the time would not be far distant when that position would be reversed, when the countries of the British Empire would be crying out for more citizens of the right breed, and when we in this country would not be able to supply the demand. If, to-day, we could give even a little help to those who were carrying on the race, the money would not be wasted. He proposed to raise the allowance for each child after the first to £50, however many children there were.

The smallest earned income—in the hands of a single person—liable to tax was now £125. Such a person received a personal allowance of £100 and an allowance for earned income of £25, but if the income was derived from investment it would pay tax on £25. This had pressed rather hardly on small taxpayers owing to the Conversion scheme. In future it was proposed that the exemption limit should be fixed for all types of income up to £125, whether consisting wholly or in part of investment income, and to avoid a sudden jump in liability to tax payable on total incomes between £125 and £140 there would be an over-riding provision by which the tax should not exceed one-fifth of the excess over £125. The cost of the relief given by the above measures would amount in a full year to £10,000,000, and in the current year to £4,500,000. It was not possible this year to deal with the 10 per cent. surtax surcharge. The restoration which it was proposed to make of the remaining half of the 1931 cuts in salaries and wages as from July 1st next, would cost in a full year £5,500,000, and in the current year £4,000,000. The cost of all the reliefs in the current year was £10,525,000. To meet this there was a disposable surplus of £11,025,000, which, on a final balance of the Budget, left a prospective surplus for the year of £500,000.

HOUSE OF COMMONS

WEDNESDAY, APRIL 10TH

Medical Officers of Health Superannuation

Captain Elliston asked the Minister of Health whether he was prepared to bring pressure on those local authorities whose failure to adopt the recommendations of the Askwith memorandum on salaries of whole-time public health medical officers meant denial of fair rates of superannuation to medical officers now approaching the age of retirement.—Sir Hilton Young replied: No, Sir. I have no power to enforce these recommendations, but in those cases in which my approval is required to the appointment of a medical officer of health, it is my practice where necessary to call the special attention of the local authority to the recommendations.

In reply to a question put later by Sir Arnold Wilson, Mr. Shakespeare stated that the Act had been put in force by 48 out of 63 county councils, 65 out of 83 county borough councils, 134 out of 273 borough councils, 6 out of 29 metropolitan borough councils, 321 out of 739 urban district councils, 243 out of 592 rural district councils, 25 out of 7058 parish councils, and 179 miscellaneous authorities. Of the authorities which had not put the Act in force, two county councils, two county borough councils, and 21 metropolitan borough councils had local Act superannuation schemes.

Detention of Disease Carrier

Mr. GROVES asked the Minister of Health under what statutory authority a farm hand at Iver, Bucks, was compelled, under a magistrate's order, to enter hospital as an alleged disease carrier.—Sir HILTON YOUNG replied: I understand that the person referred to was removed to hospital under the powers conferred by Section 124 of the Public Health Act, 1875.

THURSDAY, APRIL 11TH

Knacker's Yard at Writtle, Essex

Sir VIVIAN HENDERSON asked the Minister of Health whether he was aware that the inhabitants of Writtle, Essex, were gravely concerned by a proposal to establish a knacker's yard, for the slaughter of tuberculous animals, within 400 yards of the village, and the decision of the rural district council to sell two acres of land for the purpose; and could the inhabitants be assured that he would not approve the sale without first giving the representatives of the parish an opportunity of personally pleading their case.—Mr. SHAKESEPARE, Parliamentary Secretary to the Ministry of Health, replied: The answer to both parts of the question is in the affirmative.

Uninhabitable Houses

Mr. HUTCHISON asked the Minister of Health how many houses in the country which had been acquired by local authorities for demolition purposes as uninhabitable were still undemolished and still contained tenants who were paying rents to the local authorities concerned.—Mr. SHAKESPEARE replied: It is regretted that this information is not available. My right hon. friend may, however, take this opportunity of saying that in cases which have been brought to his notice and investigated it has been found that it has been necessary for the local authority to expend any rents received by them in order to keep the property even temporarily in tolerable condition.

Milk (Special Designations) Order, 1923

Major MILLS asked the Minister of Health if he would as a temporary or permanent measure, authorise such rural and urban district councils within the administrative county of Southampton as applied to him to grant licences to sell Grade A milk under the Milk (Special Designations) Order, 1923, in order to avoid unequal treatment of milk producers who desired to qualify for the bonus under the accredited milk scheme, in view of the fact that the Hampshire county council did not at present exercise its powers under the above order and had no meeting at which it could decide to do so until May 13th, and that at present only a small proportion of the district councils in the county could grant these licences.—Mr. SHAKESPEARE replied: My right hon. friend is in communication with the County Council upon this matter, and pending their decision he does not think it desirable to authorise any further district councils to grant licences to producers of Grade A. milk.

Bacteriological Examination of Chinese Eggs

Mr. HASLAM asked the Minister of Health if he was conducting further bacteriological examinations into Chinese eggs not in shell as imported into this country, and if such inquiries included both disease producing micro-organisms and those causing putrefaction; and if he was prepared to publish the results in due course.—Mr. SHAKESPEARE replied: My right hon. friend proposes to have certain further examinations made; the investigations have been directed both to disease producing micro-organisms and also to other non-pathogenic organisms, among which putrefactive organisms are included. My right hon. friend does not at present see any need to publish the results, but he will be happy to furnish my hon. friend with further details if he desires them.

Pasteurised Milk

Sir ARNOLD WILSON asked the Minister of Health whether he was aware that cream was frequently removed from milk before pasteurisation by large processing organisations and an equivalent amount of sterile fat added in the form of powdered milk; whether this practice was approved by his advisers; and, if so, whether he would arrange for a practical test over an extended period of the effect on children of this de-natured beverage as well as of milk.—Mr. SHAKESPEARE replied: The answer to the first two parts of the question is in the negative, and the third part does not therefore arise. I may perhaps remind my hon. friend that under the Milk and Dairies (Amendment) Act, 1922, the sale as milk of any liquid in the making of which dried milk has been used is prohibited.

Milk Supplied to School-children

Mr. R. J. RUSSELL asked the Minister of Agriculture what amount, if any, of the cost of the milk supplied to school-children was paid by the milk producer by deduction in arriving at the pool price, and what amount had been paid out of Government subsidy.—Mr. ELLIOT replied: In respect of the first 18,000,000 gallons consumed in the year ending Sept. 30th next, one-half of the loss incurred in supplying milk to school-children under the Milk in Schools Scheme is borne by the Exchequer under Section 11 of the Milk Act; the other half is borne, through the Milk Marketing Board, by the whole body of producers through the pool price for milk sales. Up to the end of February, 1935, 10,159,000 gallons had been consumed, and the total loss incurred by the sale of this gallonage at 1*s.* per gallon was £448,000, of which one-half is borne by the Milk Marketing Board. This figure, however, represents the actual cost of the scheme on the supposition that all the milk consumed by the children would otherwise have fetched the highest liquid price. In fact, but for the scheme some of the increased sales of milk to the children would have gone into low-price category manufacture for cheese and butter, realising with the Government grant under Sections 1, 2, and 3 of the Milk Act only 6*d.* a gallon. To this extent, therefore, sales of milk under the scheme have represented an increment to rather than a deduction from producers' returns.

Diphtheria at Leeds

Mr. GROVES asked the Minister of Health the cause of the heavy increase in cases of diphtheria and deaths from that disease recorded in Leeds during the year 1934, the mortality from diphtheria that year being the highest registered since 1913; whether his statistics showed if the increase in immunisation at Leeds had produced large numbers of carriers who had conveyed the disease to other children while not suffering themselves, or, alternatively, if there were any sanitary conditions in Leeds which accounted for the heavy increase in diphtheria.—Sir HILTON YOUNG replied: I am advised that the recent experience as regards diphtheria in Leeds accords with the general upward trend in the incidence of the disease which has recently affected all the large urban centres, especially those in the West Riding of Yorkshire. The answer to the second part of the question is in the negative.

MONDAY, APRIL 15TH

Telephone Facilities for Calling Doctors

Colonel HENEAGE asked the Postmaster General what response he had had to his advertisement calling attention to the opportunities for calling a doctor for a sick child when a telephone was installed.—Sir. KINGSLEY WOOD replied: I am sorry that it is impossible to distinguish, among the new orders for telephone service, which are now reaching the Post Office in large numbers, those which are attributable to a particular advertisement.

LONDON HOSPITAL.—Another £4000 is needed by the London Hospital for its new massage and electrical department which is to replace the present accommodation.

CORRESPONDENCE

THE NEED FOR MEDICAL PSYCHOLOGISTS

To the Editor of THE LANCET

SIR,—In his letter of April 8th Dr. Henry Harris makes a plea for the specialty of psychotherapy to be undertaken by men to be found in the asylum services. In the same number of THE LANCET there appears a review of "Psychology and Health" by H. Banister, Ph.D., and it is recorded that Dr. Banister is a practising psychotherapist to the Papworth Village Settlement. Dr. Banister, not a registered medical practitioner, has written a book which will attract the reader because of his command of language and the meticulous care of his construction. While the facts recorded are unlikely to find serious critics among qualified alienists, Dr. Harris is entitled to ask: "Why not go to the obvious source?"

As resident medical officer of Papworth perhaps I may be allowed to make a brief answer to this question. After defining the position of the physician as a psychologist, Dr. Banister devotes the first portion of his book to the development of the conception of a sentiment-formation tendency. So clear is the description of the integration of instinctive tendencies and emotions into sentiments and their further integration into character that one does not at first suspect the originality of the theory. This conception of the location of the origin of mental disability in the material object around which the sentiments are organised forms a working hypothesis of the greatest utility; and its importance is emphasised by the arresting statement made by Dr. James L. Halliday that 33 per cent. of persons referred to the regional examining centre at Glasgow were suffering from psychoneurosis.

To the insurance practitioner, weighed down by the information that the Minister views with concern the close correlation of the unemployment returns with the number of his certificates of incapacity, this consideration will indeed be a drop of oil on troubled waters. To the physician, charged with the re-establishment in industry of the partially disabled, it is of vital importance. Unemployment, from whatever cause, constitutes a disturbance of the object around which sentiments are normally organised. Dr. Banister's book and Dr. Halliday's report form an invitation to the alienist to leave his aisle for the ever-widening horizon of psychoneurosis.

I am, Sir, yours faithfully,

LEONARD STOTT.

Papworth Hall, Cambridge, April 12th.

To the Editor of THE LANCET

SIR,—This correspondence reveals a distressing lack of a sense of proportion. No one would be so foolish as to deny the need for more medical psychologists, but stumbling-blocks are put in the way. Thus Dr. Harris contends that "With regard to training surely there can be no doubt that the D.P.M. is merely a minimal requirement for *any doctor who is to be allowed to handle mental patients?*" (The italics are mine, but the question mark is Dr. Harris's.) If the letters M.C.O.G. replaced D.P.M. in the above sentence, and the word "obstetric" replaced "mental" Dr. Harris would have found that he had raised a hornet's nest about his ears. But because he is writing of psychotherapy no excitement is aroused.

The minimum requirement for medical practice is the possession of a medical qualification—not the possession of a variety of alphabetical appendages to one's name. Our foreign colleagues have recognised this fact and never fail to express surprise at the great variety of "sub-qualifications" available in this country. Incidentally, one would be interested to know how many of the "masters" under whom the budding psychotherapist is to sit possessed or possess a special diploma such as the D.P.M. Medical psychology is as fundamental to medicine as is physical examination. It is most emphatically not an enchanted forest reserved only for possessors of the D.P.M.

I would suggest that, in addition to a medical qualification and experience of the work, the medical psychologist needs, even more than other medical workers, a very wide range of intellectual interests. His motto must be *Nihil humanum alienum a me puto;* and his knowledge of normal psychology (and also of the philosophical problems germane to his subject) is much more valuable than experience of the major psychoses and of mental deficiency. There is no reason why any practitioner who has the time and the inclination for the work should not practise psychotherapy, for neither hypnosis nor analysis are sacerdotal mysteries requiring an initiatory ceremony.

Wide reading, far beyond the confines of medicine and medical psychology; thought; and the opportunity of treating the psychoneuroses are the essentials for the psychotherapist, whether he be the possessor of the D.P.M. or not. Last, but not least, he will do well to be a sound physician of the body as well as of the mind, for then he will be less likely to bring psychotherapy into disrepute by attempting psychological treatment of unsuitable cases. The medical psychologist is not mass-produced; he is inevitably trained individually and must be almost entirely home-made.—I am, Sir, yours faithfully,

A. PINEY.

Park-square West, London, N.W., April 12th.

To the Editor of THE LANCET

SIR,—I read Dr. Harris's letter regarding psychotherapy with interest. At a time when this question is much to the fore, and the establishment of psychotherapeutic clinics is being considered, attention should be drawn to the fact that the term psychotherapy covers a multitude of treatments—not to mention sins! To some, this type of treatment means an analysis of months or years; to others five minutes monthly, provided it occurs in a psychiatric clinic and not in general out-patients, is considered psychotherapy.

With such divergence of opinion, may I suggest that the time has come for research into psychotherapeutic methods, so ably stressed by Dr. Rees at the Royal Society of Medicine this week? It is obviously of extreme economic importance, in a crowded clinic, to determine (*a*) what patients are suitable for psychotherapy; (*b*) what is the minimum time for different types of disorders to be treated in. At present adherents of various schools express their opinions, but what is needed is an objective investigation on a large scale to compare the various treatments.

I note with some alarm that Dr. Harris demands that amongst their other virtues, psychotherapists should preferably be over 40. Yet some young patients occasionally express a preference for someone young to treat them. Truly, the lot of the psychotherapist is a hard one! Viewed with suspicion by his orthodox colleagues, he is told by the psychotherapists that qualifications count for nothing.

The analysts (often with reason) demand that he should be analysed, psychiatrists that he should hold the D.P.M.; by all that he should have the necessary character and flair; and now he has to be middle-aged as well. The one essential qualification left out by all of them is the possession of a private income.—I am, Sir, yours faithfully,

W. LINDESAY NEUSTATTER.

Wimpole-street, W., April 12th.

THE WIT OF HUGHLINGS JACKSON

To the Editor of THE LANCET

SIR,—I was fortunate in getting to know Dr. Hughlings Jackson when he was 53 and I was more than 20 years younger; and I was still more fortunate in being admitted to his friendship while I was still his house physician. During the years that followed I saw him frequently and experienced much kindness at his hands. When I first took a house, on the morning after entering on possession I was sitting alone after breakfast looking round somewhat disconsolately at the meagreness of my possessions; the bell rang, and Jackson walked in. He said he had just come to wish me luck and to see the house. It was the sort of kindness which he was always practising. The next day he came in and said that he had a sofa which he never used and he pointed out a place which he thought it might fill up, and he would be glad if I would take it away as it was really rather in his way. At the same time he brought me a case containing a dozen fish knives and forks which he wished me to have, but I was to say nothing about it, as they had been a wedding present, but he could not remember who had sent them. As he had another set, he explained that I would be really doing him a kindness if I relieved him of this one! Some years later, when I got married, he appeared as our first visitor on the morning after we returned from our honeymoon, just to wish both of us happiness and prosperity. Fortunately my marriage, instead of in any way interrupting our friendship, really cemented it, because my wife and he became just as intimate as he and I had always been, and this friendship continued until the very end, for in his last illness, when he scarcely saw anyone, he begged her to come, and always gave her a cordial welcome.

I have written elsewhere of his great consideration for others and gave as an example his particular consideration for my feelings on one occasion. A patient of his had died—a case of tabes dorsalis—and it was at the time when there was the great vogue for suspension treatment in that disease. This patient had suffered from a good deal of back pain. I went with Jackson to the mortuary where Dr. Walter Colman was making the examination, but, to my surprise, Jackson asked me to go to one of the distant wards to get some notes. I learnt afterwards from Colman that Jackson was afraid that some injury had been done to the back, and as I had carried out the suspension treatment, he feared that the examination might reveal this, so he sent me out of the way in order to spare my feelings. Fortunately, however, there was no evidence of the slightest injury, but I was naturally very much touched by such consideration.

Sir Andrew Clark used to say that there were two Yorkshiremen who had no sense of humour—Jonathan Hutchinson and Hughlings Jackson. I did not know Sir Jonathan intimately enough to be able to say whether this was or was not true of him. I knew Jackson so well that I can give the statement, so far as it concerns him, an emphatic contradiction. I think the following extract from his article on the Psychology of Joking will confirm this:—

"I think punning does not receive enough attention. In spite of Dr. Johnson's well-known dictum, we should not despise punning. Sydney Smith says that it is the foundation of all wit. Supposing three degrees of evolution, I submit that: (1) punning is the least evolved system of joking; (2) that wit is evolved out of punning; and (3) that humour is evolved out of wit. Everybody has heard of Sydney Smith's remark—that it requires a surgical operation to get a joke into the head of a Scotsman. But he spoke without distinguishing. The Scotch have a great appreciation of those highly evolved jocosities displaying the humorous, although, no doubt, a scorn of simple, lowly evolved jocosities, such as plays on words. It is difficult to form a conception of a Scotch punster; yet I have heard an Aberdonian, a physician of world-wide reputation, make a pun. Punning is well worthy of the psychologist's attention. I seriously mean that the analysis of puns is a simple way of beginning the methodical analysis of the process of normal and abnormal mentation. This, I think, I can easily show. We all have 'mental diplopia' when hearing the answer to a riddle which depends on a pun—'When is a little girl not a little girl?' Answer: 'When she is a little horse (hoarse).' The feeble amusement we have in the slightly morbid mental state thus induced is from the incongruous elements of a 'mental diplopia.' The word 'hoarse' rouses in us the idea of a well-known quadruped: at the same time we have the sensation of complete resemblance with the sense of vast difference. Here is, I submit, a caricature of the normal process of all mentation. The process of all thought is 'stereoscopic' or 'diplopic,' being the tracing of relations of resemblance and difference. To call punning a slightly morbid mental state may be taken as a small joke. But I do not think it very extravagant to describe it so; it certainly is not if it be a caricature of normal mentation. A miser has been defined as an amateur pauper; the habitual drunkard is certainly an amateur lunatic. And in the same style of speaking we may say that—well, we will say that punning is playing at being foolish; it is only morbid in that slender sense."

Jackson's teaching was very graphic because of his insight into medical problems, and the striking way he had of describing what his insight showed him. Thus, in an article on "Tumours of the Cerebellum," in which a reeling gait is too often present, his insight into the cause of the reeling is described in a most impressive way:

"Reeling is the earliest motor symptom. . . It is essentially a swaying of the trunk from back to front and from side to side. It is marked in some slight cases by the patient's walking with his legs apart: by this means small inclinations of the trunk are neutralised. The gait is worse when he walks with closed eyes. In early stages in slight reels, I believe the true fault is paresis of movements of the spine answering to the swaying of the trunk. The legs act erratically, but in an early stage they are blameless: they act erratically because they have to 'run after' the trunk to prop it up in its various over-inclinings. The legs, often blamed, are doing *more* than their duty."

Similarly, in regard to speech affection, his outlook was quite new.

"Swearing, for example," he said, "is not a part of language. It is a habit which has grown up from the impulse to add the force of passing emotions to the expression of ideas. It belongs to the same category as loudness of tone and violence of gesticulation. The distinction of these from language as an intellectual act may be best illustrated by the remark Dr. Johnson once made to a boisterous antagonist: 'Sir, you raise your voice when you should enforce your argument. . .' Curses have formed an element in all religious services: nowadays intentional cursing is obsolete: it has degenerated into meaningless swearing which, like cadence and gesticulation, is but a kind of commentary of the emotions on the propositions of the intellect. Vulgar people insert an oath at the proper intervals of their speech as a sort of detonating comma, and thus they render forcible statements which might otherwise strike their hearers as commonplace."

A good many years ago I was accused, as a disciple of Jackson's, of overdoing my admiration for him and being almost too insistent in my support of some of his doubtful doctrines. I do not think this was quite true, although I must say that I always had grave misgivings when, as sometimes happened, I did not see eye to eye with him in regard to some of his views. Someone has said that no man is a hero to his valet; but this does not depend upon any failing on the part of the hero, but on the want of capacity in the valet to appreciate the high qualities of his master. The relationship of a disciple to a great teacher is quite different. He sees in his teacher great qualities of which he has at least some appreciation, and he recognises him as being on a much higher intellectual level than himself. It is, of course, a form of healthy hero-worship, and this was the attitude of myself and, I believe, of many of his other disciples to the great personality of Jackson. It will always be a pleasure to me to think that I had the privilege of being on terms of reverent and at the same time affectionate intimacy with a man of such outstanding genius.

I am, Sir, yours faithfully,

April 8th. JAMES TAYLOR.

*** Dr. James Taylor, editor of the "Selected Writings of John Hughlings Jackson" and of his "Neurological Fragments," wrote in the latter publication an admirable biographical memoir. He was thus able at the recent Jackson memorial dinner to record many intimate details of his personality, and what he sets out above will be read with pleasure at the present juncture.—ED. L.

ASPHYXIA NEONATORUM: ITS TREATMENT BY TRACHEAL INTUBATION

To the Editor of THE LANCET

SIR,—The procedure described by Mr. Blaikley and Mr. Gibberd in your issue of March 30th, p. 736, promises to be of great practical value in the treatment of asphyxia in the new-born. Their method for dilatation of the solid lung with oxygen-carbon-dioxide gas mixture closely imitates what normally occurs shortly after birth, when the infant must somehow, and by some physiological action, bring about a phenomenally high air pressure in the smaller bronchi—far beyond that which obtains after the lung has once been dilated.

Now, what is this highly important physiological action to which every normally born infant owes its life? In considering this problem I wrote in 1903[1]:

> . . . "in children, the bronchioles dilate and contract rhythmically with inspiration and expiration. . . . At birth, before respiration has occurred, the lungs are solid and in an atelectatic condition, and at the first breath, the air inspired has to overcome the adhesion of the surface of the bronchial mucosa and of the alveolar epithelium. It is only after some time has elapsed that the lung is fully expanded and the pulmonary expansion, which occurs in spite of the tendency of the lungs to contract, is probably aided by the bronchial contraction during expiration, otherwise the chest would tend to remain collapsed if the air passed out of the bronchial tubes just as readily as it passed in."

A baby with each inspiration dilates the vocal cords and the bronchioles; with each expiration the vocal cords approximate and the bronchioles contract, so that the air is inspired more freely than it is expired, as its exit is slightly impeded, and so expiration is more prolonged than the corresponding inspiration. With forced respiration efforts the glottis and bronchioles are more dilated on inspiration and more contracted on expiration, and hence the inspired breath more definitely locked in; much as in paroxysmal asthma, when the expiration may be so prolonged that the next inspiration has to be made before the expiration is complete, and consequently the lungs become more and more distended, with the air pressure in the bronchioles and alveoli abnormally high. But it is by a precisely similar process of locking-in of the inspired air and increasing partial air pressure that the new-born infant gets the solid lung dilated up. Now, this work of Mr. Blaikley and Mr. Gibberd goes to show that a pressure of at least 20 cm. of water must be attained in the smaller bronchioles to effect this dilatation of the atelectatic lung of the new-born by artificial means; hence the futility of forcible inflation by the oxygen-gas mixture under a pressure of no more than 15 cm. —enough in after-life but wholly inefficient to expand the lung in asphyxia neonatorum. Indeed, they found that the air forced into the trachea should have a pressure of 30 cm. Surely no inspiratory effort of the infant could possibly bring about anywhere near such a high negative pressure?

It seems that the forcible respiratory efforts, with the consequent bronchiolar contractions and dilatations, are essential factors in bringing about such a degree of dilating pressure in the bronchioles. If that is true, one must realise that in such conditions the usual methods of artificial respiration are certain to fail.

A further point of interest lies in the fact that in using the authors' method "the movements of respiration are not necessary for the process of lung ventilation, which can be adequately maintained in the complete absence of respiratory movements." Quite so, for their procedure reproduces what normally occurs in the alveoli. The air pressure during normal inspiration and expiration is almost static; just as in the capillaries the circulating blood is little affected by attending cardiac systole or diastole. Differing air pressure in the alveoli and minutest bronchioles would influence the *rate* of gas exchange; hence under the forced air pressure, the baby will quickly develop a respiration-rate so rapid that it is impossible to follow it by alternating pressure in the bag; moreover, it would anyhow be futile to attempt this, for the maximum effect of quickened oxygenation has been obtained by the artificially high air pressure in the alveoli.

I am, Sir, yours faithfully,

Bristol, April 12th. PATRICK WATSON-WILLIAMS.

TREATMENT OF LOBAR PNEUMONIA

To the Editor of THE LANCET

SIR,—Even with the assistance of Felton's serum, as recommended by Dr. Davies and his colleagues in your issue of April 6th, it must be almost impossible for a pneumonia patient to recover without a full complement of sleep. Writing in the *Edinburgh Medical Journal* many years ago, a physician, whose name I have forgotten, claimed that chloral hydrate was almost a specific for acute lobar pneumonia and, in his experience, cut short the disease. He combined it with digitalis. Here, then, was a potent remedy which had the charm of producing sleep. I put it into practice forthwith, and was frankly surprised at the results obtained; cases which had seemed hopeless from the first recovered. My practice was to give 20 grains of pure chloral hydrate and half an ounce of the fresh infusion of digitalis at 9 P.M. on the first day of the illness, giving another grs. 10 an hour later if the patient were awake.

---

[1] Bristol Med.-Chir. Jour., March, 1903.

The next and following days the patient had chloral grs. 20, with the digitalis night and morning if necessary, and no other medicine; for nourishment 8 oz. of milk and half an ounce of brandy every two hours if he were awake. As a matter of fact, these patients seldom sleep more than two hours on a stretch, but the sum total during 24 hours is often 10 to 12 hours, with comfortable drowsiness between. If sleep should be prolonged beyond four hours they should be roused for nourishment, but never to take the temperature. On no consideration whatever should an alkali be given with chloral hydrate.

I am, Sir, yours faithfully,

April 11th. T. PAGAN LOWE.

SIR JOHN ROSE BRADFORD

To the Editor of THE LANCET

SIR,—In an age when octogenarians are plentiful, and even nonagenarians by no means rare, the passing of Rose Bradford will, to his many pupils and friends—the terms are synonymous—seem grievously premature. Memory takes one back to 1889 when he won the Gold Medal at the London M.D. Exam., an honour which, for several years thereabouts, was "farmed" by U.C.H. Bradford inherited the teaching of a gifted band—Jenner, Quain, Bastian, Ringer, "Freddy" Roberts, and, by no means least, Vivian Poore, a master both of clinical medicine and of epigram.

References have been made to Bradford's remarkable memory. I have often heard Bradford himself speak of this gift as a striking quality of Poore's genius, who, years after the event, would remind his listeners of the clinical features of a particular case in a particular bed in Ward IX of the old U.C.H.

Of Bradford's early triumphs in physiology, and his almost precocious capture of the F.R.S., others better qualified have spoken. We remember him as the quiet helper and steadfast friend, and a personal instance will serve as an illustration. I had not seen him for nearly ten years when I unexpectedly met him in France in 1918. In the uniform of a major-general, and wearing the ribbons of the K.C.M.G. and C.B., his spare, slightly stooping figure contrasted somewhat strangely with those to which one had become accustomed during four years of war. And, in a moment it was Bradford and no other. In the same quiet voice he expressed the same measured concern for what I was doing, and asked how things were going with me. It was as if we had parted but the week before—so unfailing was his memory, so unswerving his sympathy.

And U.C.S., U.C.L., and U.C.H. will for many generations bear the imprint of the character and example of the most distinguished and lovable personality who has ever crossed the threshold of all three. I am, Sir, yours faithfully,

Bury St. Edmunds, April 13th. ERNEST STORK.

PANEL AND CONTRACT PRACTICE

Sickness in a Large Industrial Group

AT the annual meeting of the National Federation of Employees' Approved Societies a claim was made by the president, Mr. Henry Lesser, that the sickness statistics compiled each year by the Federation are unique in this country for the picture they give of occupational sickness. Details for 1934 are not yet available, but he was able to give the benefit per member as 11·21 days for men and 10·35 days for women, being a slight improvement in the one case and a slight setback in the other. The number of claims paid in 1934 was, however, lower than in 1933, both for men and women. Expenditure on influenza was notably less in 1934 than in 1933, but in almost every other group of diseases there were small increases. Incapacity among men from nervous diseases had, he said, increased steadily from 0·99 days per member in 1929 to 1·59 days per member in 1934; in women, on the other hand, the amount of illness from this cause had remained stationary. Reviewing the sickness experience of the last six years he found no indication of any lowering of the general standard of health among the members; the rate of sickness remained slightly below that of 1929. This encouraging result might, Mr. Lesser remarked, be attributed "to some extent at least" to improved medical service provided under the National Health Insurance Acts.

A Costly Omission

Clause 9 (12) of the terms of service requires an insurance practitioner to keep and furnish records of the diseases of his patients and of his treatment of them in such form as the Minister may determine. Some practitioners appear still to be under a misapprehension as to the meaning of the words "to keep." Reference to the context will show that the requirement is to keep the record in the sense of compiling it, and the requirement to furnish is equally insistent. A practitioner in the North of England is likely to have this fact brought rather sharply to his notice if the recommendation of the local insurance committee is adopted by the Minister of Health. On two previous occasions this practitioner had been fined owing to his failure to transmit forms of medical record on demand. Between June 22nd and Dec. 10th, 1934, repeated applications were made to him without avail for the return to the committee of the medical records of 42 insured persons removed from his list, and between Dec. 10th, when the matter was referred to the medical service subcommittee for investigation, and Jan. 24th, 1935, further application had been made without avail for the return of 49 more records. The practitioner admitted his omission to return them, giving as the reason for his failure to do so that he had been ill and had from time to time employed a locum tenens to help him in his practice, but preferred to attend to the clerical side of his work himself. Notwithstanding his undertaking to return the records within a week or so, and his statement that he realised the serious nature of his omission, the insurance committee decided to make representations to the Minister that, owing to his repeated failure to comply with the terms of service, the conditions on which the money for defraying the cost of medical benefit is payable to the committee had not been fulfilled and that the sum of £75 should be withheld, such sum to be recovered by deduction from his own remuneration. This appears to be a case where it would have been cheaper for the practitioner to have obtained clerical assistance.

Personal Attendance Overdone?

A London practitioner has incurred trouble for himself by an endeavour to do his best for the patient instead of handing over his responsibility to a hospital.

The patient was seen by this practitioner and his partner alternately twice in October and twice early in November. On the occasion of the first consultation he complained of sore-throat and cough; his chest was examined and his heart was found to be in a weak state; the cough was considered to be due to pharyngitis. On Nov. 6th the man attended the surgery and was seen by the partner who, on examination, found him suffering from palpitation and shortness of breath on exertion, bruit of mitral disease with dilatation of the right side of the heart, moist râles all over the chest, temperature normal, sputum greyish, and œdema of feet. The partner diagnosed heart failure and advised bed, pointing out the vital importance of rest. Visits were made to the patient four times up to Nov. 27th, and on the 29th idem he attended at the surgery and was instructed to return to bed. Further visits were paid on Dec. 3rd, 6th, and 10th, on the last of which dates, after an interview with the patient's brother, the partner arranged for the removal of the patient to a local hospital. After admission raised evening temperatures suggested the desirability of X ray and sputum tests; the former indicated a tuberculous condition of the lung and the latter the scanty presence of tubercle bacilli. The patient died in hospital on Jan. 13th. His brother, who made a complaint to the insurance committee, did not allege neglect against either the practitioner or his partner in so far as their treatment of the patient was concerned; but he thought that if the existence of tuberculosis had been diagnosed earlier life might have been prolonged. He suggested that the partner was negligent in not having arranged earlier for admission to hospital, and referred to the fact that other residents in the house where his brother lodged were not aware of the necessity for precautionary measures against infection.

In his evidence to the medical service subcommittee the practitioner stated that symptoms associated with mitral stenosis, from which the insured person was suffering, would produce exactly the symptoms found. There were no symptoms, such as night sweats, indicative of the existence of tuberculosis, and having regard to the diseased condition of his heart the cough was regarded as due to that condition. The insured person seems to a large extent to have disregarded the advice to have complete rest in bed, inasmuch as on every occasion on which he was visited he was found out of bed. The committee expressed themselves satisfied that both the practitioner and his partner gave proper and sufficient attention to the case and that they were in no way negligent in not arranging earlier for the admission of the patient to hospital. On the contrary, the fact that the partner continued to treat the insured person in respect of his very serious heart condition, rather than absolve himself of responsibility by sending the patient to hospital, suggested that he was taking a genuine interest in the case.

SOCIETY FOR PROVISION OF BIRTH CONTROL CLINICS. A lecture on the theory and practice of contraception will be given to medical practitioners and students by Dr. Gladys Cox on Friday, May 3rd, at the Walworth Women's Welfare Centre, at 6 P.M. At the centre demonstrations will be given at 6 P.M. and at 7 P.M. on Friday, May 10th, and at the same hours on Friday, May 17th. The fee for the lectures and demonstrations at the centre is 5*s*.; they are open to medical practitioners and students who have completed their gynæcological course, and those wishing to be present are asked to signify at which of the alternative hours they wish to attend.

MEDICINE AND THE LAW

Damages for Dead Person's Sufferings

UNACCUSTOMED consequences are flowing from the new legal rule that a living person may obtain damages for pain and suffering negligently inflicted on a dead person. It remains to be seen how far the rule will go in the field of professional negligence. Meanwhile, it is having its natural application in connexion with traffic injuries, as is illustrated by the case of Rose *v.* Ford recently decided at Birmingham assizes. A woman was injured by a careless motorist; her leg had to be amputated and, four days after the accident, she died. Her father sued the motorist for damages. Before 1934 there was a legal maxim that personal actions died with the person concerned; the judges had evolved the rule that in a civil court the death of a human being could not be complained of as an injury. To this rule an exception was made by the Fatal Accidents Act, sometimes called Lord Campbell's Act, in 1846. Under this statute it became possible for a wife, husband, parent, or child to bring an action for damages where death had been caused by wrongful act, neglect, or default. In the Birmingham case the father obtained £300 damages under this Act as he could have done before 1934. But he also obtained £500 damages under the new law. Had his daughter lived, she would have been entitled to damages for the pain and suffering caused by the motorist's negligence and for the loss of her leg. The Law Reform (Miscellaneous Provisions) Act of last year introduced the general principle (subject to certain exceptions and limitations) that on death all causes of action on which the dead person might have sued are henceforth to survive for the benefit of the dead person's estate. Thus the father could obtain the £500 for the four days of pain and suffering endured by his dead daughter and for the loss of her leg. Counsel for the defendant motorist sought to resist the claim or to diminish the damages by an argument which was really an attack upon the new law. Suppose, he said, a man has left all his property to the British Museum and is run over and injured by a motorist and dies of his injuries a week later; would it not be absurd that an institution like the British Museum should be entitled to stand in the dead man's shoes and to recover damages for personal injuries and suffering which an impersonal body cannot feel? The argument, however, met with no success.

In one respect the plaintiff failed in the Birmingham case. The father had claimed damages not only for his daughter's sufferings and the amputation, but also for the shortening of her expectation of life. Under this last heading Mr. Justice Humphreys declined to allow the father any damages because there was, he said, no evidence that she suffered mentally on account of that shortened expectation. Not long ago the Court of Appeal confirmed a judgment by Mr. Justice Acton (Flint *v.* Lovell) awarding £4000 for shortened expectation of life to a man of 70 who, by injury in a motoring accident, had lost the prospect of an "enjoyable, vigorous, and happy old age," and was now, according to the medical evidence, not likely to live for another year. If a living person can thus obtain damages for shortened expectation of life, will not a similar course of action survive to the estate of a dead person? It is worth noting that Sir Frederick Pollock, a high authority, has lately criticised the Court of Appeal for its attitude in Flint *v.* Lovell. The veteran jurist has no objection to the calculation of shortened expectation by reference to a sufficiently large average; the basis, as he says, is familiar enough in contracts of life insurance. But he doubts if it is possible for any human tribunal to attach any definite meaning to the supposed detriment of the shortening of life—"or, for that matter, to say whether death, when it happens, is itself a bad or a good thing." There must always be a danger, as Lord Justice Roche hinted in Flint *v.* Lovell, that to make the shortened expectation of life a distinct head of damages is to compensate the plaintiff twice over for what is really the same detriment. To return, in conclusion, to the imaginary case of the man who has left his property to the British Museum, it would certainly seem anomalous if the Museum should get damages for the accident which shortened his expectation of life when it is thereby receiving his property all the earlier.

Doctor's Delay in Report to Police

At a recent inquest at Camberwell the coroner commented on a doctor's duty to give prompt information to the police after having been called in to attend to someone found shot. The inquest was upon the death of Mrs. Edwards, aged 72, whose husband, Harry Hans Edwards, aged 80, is now remanded on a charge of having murdered her. There was evidence that the deceased was addicted to alcohol and came home one night the worse for liquor. Next morning about 6.30 a daughter heard a scream and, going to her parents' bedroom, found her mother lying across the bed and her father standing near. A doctor was summoned. He found that Mrs. Edwards had two wounds in the chest; Mr. Edwards had a revolver which the doctor persuaded him to hand over. The doctor went home and saw some patients who had called; he did not tell the police till after 10 A.M. and the police did not visit the Edwards's house till 10.50. The coroner pointed out the importance to the police of being able to examine the exact position and surroundings of the body at the earliest possible moment. He reminded the doctor of his duty to communicate with the police promptly, though he said the omission on this occasion had not greatly mattered. Coroners and police are naturally preoccupied with the dead; medical practitioners can hardly be blamed if they attend to the living. Nobody but the medical practitioner is in a position to assess the relative claims.

OBITUARY

JOHN ATHELSTAN BRAXTON HICKS,
M.D. Lond., D.P.H. Camb.

We announced last week the death on April 7th from pneumonia of Dr. John Braxton Hicks, pathologist in charge of the L.C.C. group laboratory at Lambeth.

John Athelstan Braxton Hicks was born in London the son of Mr. Athelstan Braxton Hicks, was educated at Epsom College, and received his medical training at Westminster Hospital. He graduated at the University of London as M.B., B.S. in 1907, obtaining honours in pathology, and proceeded to the M.D. degree three years later. In the same year, 1910, he took the D.P.H. at Cambridge, and was appointed pathologist to the Seamen's Hospital, Greenwich.

His work there justified the invitation to return to the Westminster Hospital, and he served the institution zealously in many capacities. He was assistant pathologist and curator of the museum for a period, was resident obstetric physician, and in 1917 was in general charge of the venereal cases. He was lecturer in the medical school on morbid histology and pathology, and he also compiled a card catalogue for the museum based on the one previously made by the late Charles Stonham. For two years, 1911–12, he was pathologist at Queen Charlotte's Lying-in Hospital. In 1913 he took the diploma of M.R.C.P. Lond., and arising out of his various opportunities for pathological observation, made many communications of clinical value to medical literature, including papers published in the *Proceedings* of the Royal Society of Medicine, the *British Medical Journal*, and *The Lancet*. He was appointed reader and associate examiner in pathology at the University of London, and at the time of his death was pathologist in charge of the group laboratory, L.C.C., at Lambeth Hospital.

Braxton Hicks was a pathologist of high standing, and his work was especially marked by the endeavour to make his findings of clinical value. We have received from his colleagues at Lambeth Hospital the following estimate of the man and his services to medicine: "The news of Dr. Braxton Hicks's death came as a grievous shock to his colleagues at Lambeth Hospital, where he was immensely popular with medical and nursing staff alike. He was recognised for what he was, a real 'character.' To his pathological work he brought wide experience, keen interest, and great thoroughness, and his reports, especially in an uncommon or difficult case, were sure to be full, detailed, and enlightening. He was a keen and well-qualified clinician and few things delighted him more, when in the wards collecting pathological specimens, than to be asked his clinical opinion of a case. His view, modestly though expressed, was seldom wide of the mark. In his laboratory he took refuge behind a brusqueness of manner which quite failed to hide from the discerning his innate generosity, for, however busy he was, his help was never asked in vain. He was sensitive and not one with whom it was wise to take liberties, but few could deliver so efficient a rebuke with so little rancour. He little guessed how much his 'billets doux' of good-humoured 'strafe' were prized by their recipients. He will long be remembered as a first-rate pathologist, a loyal colleague, and a most lovable personality."

Dr. Arthur Davies writes: "As a fellow student of John Braxton Hicks, may I be allowed to pay tribute to him. Coming to Westminster from Epsom with a high reputation for scholarship, he quickly impressed his contemporaries with the quality of his industry and ability. He showed himself to be worthy of his distinguished forbears in obstetrics and in forensic medicine, and gave early promise of eminence in pathology, gaining honours in the University of London M.B. examination. There was no doubt in our minds that he was a man of outstanding merit, and that a career of unusual distinction lay before him. This was confirmed by the success he subsequently achieved. Winning his spurs as pathologist to the Seamen's Hospital, he was invited to return to Westminster as assistant to our revered chief, Richard Grainger Hebb. The energy and loyalty with which he served our 'Master' still further endeared him to Westminster men. Later he succeeded to the directorship of the laboratory and continued to devote himself with the greatest assiduity to the work that devolved on him during a period of great development in the scope of investigation and research, and for which he was so well endowed. The qualities that distinguished him as a student remained remarkably constant, and to few is it granted to maintain such a standard of high endeavour. His fellow students will continue to remember and revere a loyal brother, and a distinguished son of their medical school."

GILBERT BERTRAM WARBURTON,
Ch.M. Manch., F.R.C.S. Eng.

THE death is announced on March 25th of Mr. G. B. Warburton, who recently retired from his position of senior surgeon at the Royal Manchester Children's Hospital on account of continued ill-health. He received his education at the University of Manchester, and graduated M.B., Ch.B. Manch. in 1907. He was house surgeon to the Manchester Royal Infirmary, and in 1912 took the diploma of F.R.C.S. Eng., and in the following year proceeded to the degree of Ch.M. In due time he was appointed assistant surgical officer in the out-patients' department of the Infirmary, and resident surgical officer, and later, as surgeon to the Royal Infirmary, became surgical tutor in the medical school.

At the outbreak of war Warburton was resident surgical officer at the Infirmary, and in 1917 joined the R.A.M.C. and served in Egypt until the end of hostilities. He attained the rank of major, and was appointed surgical specialist in the 76th Casualty Clearing Station of the Egyptian Expeditionary Force and was more than once mentioned in dispatches. On his return to civil life he was appointed surgeon to the Royal Manchester Children's Hospital, and he worked in connexion with this institution until his health broke down last year. Through his experiences at the hospital he became deeply interested in hare-lip and cleft-palate surgery, while he also did valuable work as visiting surgeon to the Bethesda Home for crippled children, and as consulting surgeon to the Manchester and Salford Society in aid of crippled children. Since 1922 he had been visiting surgeon to the Withington Hospital and took an active part in the development of this hospital, which has proceeded rapidly since the transfer of the institution to the control of the Manchester City Council.

Mr. Warburton's widow only survived him by a few days, and he leaves three sons.

MEDICAL NEWS

Royal College of Physicians of London

At a meeting of the College held on April 15th, Lord Dawson of Penn was re-elected president. Dr. O. F. F. Leyton and Dr. F. M. R. Walshe were appointed Examiners to the Conjoint Board in medicine and ophthalmic medicine respectively.—Lord Horder was appointed a representative of the College on the National Council for the Disposition of the Dead; Surgeon Vice-Admiral Sir Reginald Bond, M.B., a representative of the College on the Professional Classes Aid Council, and Dr. T. W. Wadsworth a delegate to the twenty-first annual conference of the National Association for the Prevention of Tuberculosis to be held at Southport, June 27th–29th, 1935.

Diplomas in Ophthalmic Medicine and Surgery were granted, jointly with the Royal College of Surgeons, to the following candidates :—

Harbans Lal Anand, Edmund Johnston Baldwin, Godfrey Dacre Jennings Ball, Allan Henry Briggs, Rochiram Udhandas Hingorani, Vincie Vernon Hilton Hoakai, Alice Bowen Laker, Thomas Boyd Law, Lionel Arthur Lewis, Frederick Maxwell Lyons, Abraham Mellick, Jainti Dass Saggar, Lajpat Rai Sarin, Captain Peter Shannon, I.M.S., and Edward Wolstein.

University of London

At recent examinations the following candidates were successful :—

D. P. H.

Part I.—V. F. Anderson, Lalage R. A. Benham, J. H. Blakelock, Edith J. R. Browne, Hilda L. Byett, H. S. Davies, C. M. Dighe, David Erskine, W. G. Evans, Mohomed Farooq, O. M. Francis, H. A. Gilkes, J. V. Hurford, J. T. R. Lewis, Edyth L. Morris, Vaithianather Nada Rajah, R. M. M. C. Orpwood, L. M. Ram, C. J. Sanderson, Hubert Smith, Thomas Standring, E. W. Taylor, V. T. Vagh, J. D. V. Wijeyaratne, W. W. Wildman, and R. A. Wilson.

British Dental Association : New Headquarters

The new headquarters of the British Dental Association at 13, Hill-street, Berkeley-square, were formally opened by Mr. Geoffrey Shakespeare, M.P., parliamentary secretary to the Ministry of Health, on April 12th, in the absence of the Minister of Health, through illness. Mr. W. Graham Campbell, who presided, was supported by Mr. G. Northcroft, chairman of the representative board, Mr. Bryan Wood, chairman of council, Mr. Walter Wood, treasurer, Sir Norman Bennett, Mr. E. Hackforth, of the Ministry of Health, Mr. W. G. Senior, dental secretary, and members of the representative board. Mr. Campbell, in asking Mr. Shakespeare to open the building, said that the Association had moved from lodgings in Hanover-square to a house in Bloomsbury, and thence to a mansion in Mayfair. It had outgrown the quarters at Russell-square which had seen so many activities since 1920, and further accommodation was urgently needed for its increasing responsibilities. They owed much to Mr. F. J. Pearce, chairman of the housing committee, for his search for new quarters and his supervision of the alterations to the new building. Mr. Shakespeare said they were fully cognisant at the Ministry of Health of the valuable work which public dentistry played in the health of the community and the responsible part which the British Dental Association took in its organisation. He had recently been reading the history of dentistry which Mrs. Lindsay, the librarian, had written, and had been greatly interested in its developments. He paid a tribute to the importance of the school dental service and referred to the pioneer work in that field of W. M. Fisher, of Dundee. Sir Norman Bennett then asked Mr. Shakespeare to open formally the Robert Lindsay Library. When, he said, the British Dental Association moved to Russell-square in 1920 Mr. Lindsay was appointed its first dental secretary. He was a man of great energy and played a conspicuous part in the passing of the Dentists Act of 1921, and the subsequent developments of public dental service as an additional benefit under the Health Insurance Acts. He devoted his life to the Association and it was fitting that his name should be commemorated in the library of which his wife was now curator.

Royal Naval Medical Club

The annual dinner of this club will be held at the Trocadero Restaurant, W., on Friday, April 26th, at 8 P.M. The general meeting will be at 7.30 P.M. The hon. secretary *may be addressed at the* Medical Department, Admiralty, London, S.W. 1.

St. Mary's Hospital Institute of Pathology

A course on pathological research in its relation to medicine is to be held during the summer session at the institute of pathology and research at St. Mary's Hospital, London, and opens on May 2nd with a lecture on the determination of the true from the false in medicine and elsewhere, by Sir Almroth Wright, F.R.S., principal of the institute. The next lecture will be delivered on May 9th by Prof. E. D. Adrian, F.R.S., on the electrical activity of the brain, and on May 16th Dr. Igor N. Asheshov, formerly director of the bacteriophage laboratory at Patna, will speak on bacteriophage. On May 23rd the lecturer will be Dr. C. H. Andrewes (the cancer problem: some fresh clues); on May 30th Dr. R. G. Canti (cinematograph demonstration of the cultivation of living tissue); on June 6th, Sir Henry Dale, F.R.S. (the active substances in ergot); and on June 13th Dr. J. Henderson Smith (virus disease in plants). The lecturer and subject for June 20th will be announced later. The lectures are open, without fee, to members of the medical profession and students of the medical schools, and will take place at 5 P.M.

Chesterfield Royal Hospital

Mr. G. A. Eastwood, a former Mayor of Chesterfield, has left £10,000 to this hospital for building new medical wards.

British Health Resorts Association: Conference at Buxton

The corporation of Buxton will open on Friday, April 26th, a new clinic for the use of persons of moderate means who are suffering from various forms of rheumatic disease. Lord Horder will perform the opening ceremony, and the Association has been invited to hold a conference the next day. The discussion will be on the spa treatment of crippling conditions in children and adults, and will be opened by Dr. R. G. Gordon, of Bath, speaking from the physiological point of view, followed by Dr. A. H. Douthwaite and Mr. A. G. Timbrell Fisher. At the Devonshire Hospital there will be a demonstration of the various methods employed; the use of pools, manipulation baths, douches, whirlpools, &c., in orthopædic treatment. There will also be a discussion opened by Sir Landon Ronald on the place of amusement in the health resort; Mr. St. John Ervine and Mr. L. du Garde Peach also speaking.

West Sussex Contributory Fund

At the annual meeting of the West Sussex Associated ospitals Contributory Fund, reference was made to the laims of married members for the nursing association ebate, but for which the fund would be unable to pay nother 1*s.* a day on in-patients to the associated hospitals. he rebate was claimed last year by no fewer than 4332 narried couples, bringing about a loss to the fund of £936. he report submitted to the meeting showed a membership f 22,000. Associated hospitals received £4974 for 882 n-patients and 2298 out-patients. Non-associated hositals received £710 for 151 in-patients and 75 out-patients. ayments to the West Sussex county council for treatment f 843 children of members amounted to £44.

Board of Control

Dr. G. W. J. Mackay and Dr. Flora H. M. Calder have been appointed commissioners of the Board of Control (Lunacy and Mental Deficiency), on the retirement of Dr. S. E. Gill and Surgeon Rear-Admiral E. T. Meagher.

Dr. Mackay received his medical education at Edinburgh, where he graduated M.B. in 1921. In 1926 he took the diploma in psychological medicine. He acted as assistant medical officer at St. Andrew's Hospital for Mental Diseases, Northampton, and was deputy medical superintendent to the City Mental Hospital, Nottingham, before taking up his present post as medical superintendent of the Sandhill Park Institutes, Taunton. He has written on luminal in epilepsy and on glucose tolerance curve in that disease.

Dr. Calder was also educated at Edinburgh, where she graduated M.B. in 1923, proceeding to the M.D. in 1929. She obtained the diploma in psychological medicine in 1929, and is also a member of the Middle Temple. She is at present second senior assistant at the County Mental Hospital, Winwick, Warrington.

Medical Defence Union

At a council meeting last week Dr. Robert Forbes was unanimously appointed secretary of the Union in succession to Dr. James Neal, recently deceased.

Dr. Forbes was born at Wishaw in 1893, and graduated in medicine at Glasgow University in 1915, having already held a house surgeoncy in the Royal Victoria Infirmary. After acting as assistant and locum in the Kingdom of Fife and in the county of Durham, he was granted a commission in the R.A.M.C. In this organisation he was associated with Prof. Lovatt Evans in the administration of gas defensive arrangements. His original unit was the 137th Field Ambulance. On demobilisation he entered into partnership with Dr. John Galloway at Gateshead-on-Tyne, becoming assistant surgeon, and ultimately hon. consulting surgeon to the Gateshead Children's Hospital. He engaged himself prominently in the civic and public work of the Tyneside, and was well known throughout the North of England. In medico-political matters he took an active part, becoming chairman of the Gateshead division, a vice-president of the North of England branch, and a member of the Gateshead insurance and panel committees. He was instrumental in establishing many public medical services in the area, and took part in several successful struggles to secure adequate rates of remuneration for the colliery surgeons of that district. After 14 years of general practice Dr. Forbes was invited to become deputy medical secretary of the British Medical Association, a position which he is now resigning to take up his duties with the Medical Defence Union. While deputy medical secretary Dr. Forbes also acted as secretary to the ethical, insurance acts, medico-political, and dominions committees. At the present time he is a member of the Harrow urban district council and a Justice of the Peace.

Society for Relief of Widows and Orphans of Medical Men

At the quarterly court of directors, held on May 10th, Mr. V. Warren Low, the president, being in the chair, the deaths was reported of three members and of three widows in receipt of grants. One had been on the funds for 22 years and had received in grants £1870; another for 11 years with total grants of £880. A donation of £41 19*s.* 7*d.* was reported from the Bovril Medical Agency. Three new members were elected. Membership of the Society is open to any registered medical practitioner who is at the time of his election residing within a 20-mile radius of Charing Cross. The annual general meeting will be held on May 22nd. Particulars of membership from the secretary, 11, Chandos-street, London, W.1.

A Medical Tour

In connexion with the 150th anniversary of the Allgemeines Krankenhaus, Vienna, a special tour has been arranged that will afford medical men and their friends an opportunity of taking part in the celebrations. The tour is planned to last from May 11th to May 23rd. Starting from London on the afternoon of Saturday, May 11th, the visitors will arrive on Sunday night, and be plunged immediately into the sessions of the medical societies of Vienna, where clinical meetings have been arranged on numerous subjects. The working side of the tour, as planned, is relieved by excursions to places of interest in Vienna and its vicinity, and in particular it is mentioned that an optional method of terminating the proceedings by a visit to Bad Gastein will be found pleasurable. The inclusive price for the tour is, roughly, £32, and full information and details of other expenditure can be obtained from the Austrian Federal Railways, 31, Lower Regent-street, London, S.W.1.

Russian Congress in Physiotherapy

The third All-Russian congress of physiotherapy will be held at Odessa from August 25th to 30th. The principal subjects for discussion will be hyperergy and physical therapy; acute infectious diseases and physical therapy; consequences of injuries and physical therapy; the vegetative nervous system and physical therapy; short waves in biology and medicine; the significance of skin in the mechanism of physiotherapeutic actions. The principal speakers will include Prof. Brustein (Moscow), Prof. Anikin (Moscow), Prof. Nilsen (Sevastopol), Prof. Broderson (Leningrad), Prof. Plotnikov (Moscow), and Prof. Rachmanov (Moscow). Further information may be had from the president of the committee, Prof. Brustein (Moscow, U.S.S.R., Serebrjanny per. 5, room 7). It is suggested that travelling arrangements should be made through the "Intourist" travel bureau, Bush House, W.C.2.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
FRIDAY, April 26th.
Epidemiology and State Medicine—Disease in Children. 8.30 P.M. Special Discussion: The Problems of Prophylaxis in Pulmonary Tuberculosis. Openers: Dr. A. S. MacNalty and Dr. Gregory Kayne, Dr. Charles Miller and Dr. Reginald Lightwood; and Dr. D. A. Powell (Society of Medical Officers of Health). Society of Medical Officers of Health have been invited.
Urology. Week-end Meeting in Paris. 9 A.M. 1. Visit to Hôpital Lariboisière, conducted by Dr. Heitz-Boyer. 2. Visit to Hôpital Saint-Joseph, conducted by Dr. Papin.
SATURDAY.
Urology. Meeting in Paris continued. 9 A.M. 1. Visit to Hôpital Necker, conducted by Prof. Marion. 2. Visit to Hôpital Saint-Louis, conducted by Dr. Gouverneur.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, W.
THURSDAY, April 25th.—8.30 P.M., Dr. Emanuel Miller: The Medico-Legal Aspects of Aberrations in Adolescence.

worthy in this connexion that the one medical department was much more generous with its neurosis labels than the other, although the character of their material was supposed to be identical.

The interplay of functional and organic disease is so complex, and our knowledge of the former so incomplete, that an investigation such as this can hardly be expected to take us very far. But Boye's publication may at least encourage the recorders of hospital cases to give precision to their verdicts.

REDUCTION OF INFANT MORTALITY IN IRELAND

OUR Dublin correspondent writes: "Speaking at the conclusion of the debate on the estimates for his Department in the Dáil last week, Mr. Sean T. O'Kelly, Minister for Local Government and Public Health, gave some further particulars as to the infant mortality in urban areas. In his opening statement he had said that the general infant mortality had diminished from 65 per 1000 births in 1933 to 63 per 1000 in 1934, the previous average for five years being 69. He now added that the rate in all urban areas had decreased from 87 in 1933 to 78 in 1934, while the rate in rural areas had increased from 52 to 53. The four cities had shown the following decreases: Dublin, 83 to 79; Cork, 89 to 79; Limerick, 132 to 77; and Waterford, 102 to 88. The causes of this very pleasing improvement are not obvious, but some credit should be given to the extension of infant welfare schemes."

AN "L" OF A DIFFERENCE

Colonel James K. McConnel, author of "Adjustment of Muscular Habits," an excellent little book dealing with lines of treatment suggested by its title, writes as follows:—"In the reports concerning the House of Lords inquiry into the Osteopaths Bill, mention has been made of McConnell and Teal's text-book, 'The Practice of Osteopathy.' It would be a great kindness to me and others if you would allow me to mention that the part author of 'The Practice of Osteopathy' is one Carl Philip McConnell, I believe an American subject."

The book was written by Carl Philip McConnell and Charles Clayton Teal, and was first published about 30 years ago in Kirksville, Missouri, a later edition having appeared in 1920.

NEW PREPARATIONS

ERGOMETRINE.—Messrs. Burroughs Wellcome & Co. announce the commercial issue of the new ergot alkaloid, ergometrine, the isolation of which was described by H. W. Dudley and Chassar Moir a month ago (Brit. Med. Jour., April 6th, p. 520).

Four preparations of the alkaloid are issued for therapeutic use: 'Tabloid' Ergometrine, 0·5 mg. for oral administration; 'Wellcome' Solution of Ergometrine, 0·5 mg. in 2·5 c.cm. for oral administration; 'Tabloid' Hypodermic Ergometrine, 0·25 mg. for intramuscular injection; 'Tabloid' Hypodermic Ergometrine, 0·05 mg. for intravenous administration. The alkaloid used in these preparations is of a high degree of purity and crystallises readily from a number of solvents, as described in Dr. Dudley's later communication (Brit. Med. Jour., April 13th).

Ergometrine used during the puerperium rapidly causes contraction of the uterus. Given orally, in a dose of 0·5 mg. to 1 mg., ergometrine produces contraction after an interval of 6½ to 8 minutes, the contractions being identical in mode of onset and general character with those produced by active liquid extracts of ergot. Given by intramuscular injection, in a dose of 0·25 mg. to 0·5 mg., it produces strong uterine action in 3½ to 4½ minutes. Given intravenously, it produces in doses of 0·05 mg. a strong response in 110 seconds and in doses of 0·1 mg. in 65 seconds.

USEFUL CIRCULARS

FROM the Crookes Laboratories, Park Royal, London, N.W., comes a short pamphlet setting out the use of intravenous solutions of saline glucose and other infusions, and suggesting that the extensive use of collosol transfusions at home and abroad affords evidence of the absolute reliability of the solutions. The literature of the subject is carefully reviewed, and the construction of the collosol transfusion ampoule is clearly explained. Additions to the list of collosol solution are in preparation for use in cases of collapse.

By the Boots Pure Drug Co., Ltd., Nottingham, two booklets have been published through the publicity department of the firm giving serviceable information in simple form:—

1. *Special Medical Products.*—This pamphlet informs us of the composition and designed employment of a large number of pharmaceutical preparations which are in regular use and most of which from time to time have been noted in our columns. It is written as such circulars should be, for claims when made are reasonable and the details accurate.

2. *Chloramine Antiseptics.*—Various chloramine antiseptics, though alluded to in the first pamphlet, are here dealt with in detail. Chloramine-T is indicated in the treatment of all external infectious conditions, and a 0·5 per cent. solution is stated to be usually found adequate. In applications for the nose and throat and urethra, solutions of half that strength have been employed with success, while a 0·1 per cent. solution is recommended for use in eye infections. Solution tablets are supplied in various strengths. Dichloramine-T (toluenesulphondichloramide) can be employed where a constantly renewed antiseptic action over a long period is needed, and is therefore indicated, for example, in the treatment of such conditions as carbuncles and burns. Halazone (sulphondichloramino benzoic acid) is a chlorine compound for the sterilisation of individual quantities of drinking-water. It is supplied in tablets which quickly disintegrate and dissolve, but to obtain complete sterility the water should be allowed to stand for at least half an hour.

A MUNICIPAL YEAR BOOK

Sir Hilton Young contributes a preface to the 38th edition of the Municipal Year Book which has grown during the year by 80 pages, the total now numbering 1644. The increase has made the volume by no means bulky or unwieldy, the main sections of the book being divided by carton partitions carrying thumbnail labels which make reference pleasant and easy. In some directions the book has been improved for general reference; all national authorities, for instance, have now been brought within the compass of a single section, and in the sections dealing with different classes of authorities cross-references are given to the principal statutory provisions and the relevant legal decisions of 1934. Much of the descriptive material throughout the book has been rewritten; and for medical purposes it is gratifying to find the names and addresses of public analysts and of coroners, and a list of institutions appropriated in pursuance of the Local Government Act of 1929. Finally, a comprehensive review is given of leading law cases affecting local government during the past year. The Year Book is published by the Municipal Journal Ltd., Clement's-inn, London, W.C.2, at 30*s.*

PUBLIC SCHOOLS YEAR BOOK.—The forty-sixth yearly issue of this book shows little change except an alteration of title, to call attention to the fact that the book now contains full official information not only about public schools but about preparatory schools. This innovation was introduced last year and has given rise to much satisfaction. The Year Book is issued by H. F. W. Deane and Sons, The Year Book Press, Ltd., at 10*s.* 6*d.*

ADDRESSES AND ORIGINAL ARTICLES

MATERNAL MORTALITY [*]

By Eardley Holland, M.D. Lond., F.R.C.S., F.R.C.P., F.C.O.G.

OBSTETRICAL AND GYNÆCOLOGICAL SURGEON, LONDON HOSPITAL

The failure of the maternal mortality-rate to yield one decimal point to the sustained attack which has been directed against it, but its tendency rather to react in the opposite direction, has endowed it with an air of mystery and malignity. The 1933 figure of 4·5 per 1000 is 7 per cent. higher than the figure for the preceding year, and 15 per cent. higher than that of twenty years previously. It is not only the rising figure which is so disturbing to the people of this country, but also the fact that our mortality figure is about 40 per cent. higher than that of the Netherlands—a country whose statistical methods in this respect are comparable with our own.

There is, however, nothing obscure about maternal mortality. Its ætiology, both in principle and in detail, is well known, and the way in which it can be remedied is, to a certain section of the medical profession at all events, perfectly clear. There is no lack of knowledge, but only an obstinate neglect of the application of known facts.

Ineffective Measures so far Taken

The manner in which the problem has been attacked during, say, the past twenty years may be summarised as follows. Let me begin with the professional obstetricians. They have put up a good fight; but having no control of funds and little influence in directing public health policy, their success has been small. They have induced the General Medical Council to impose a minimum period which students must spend in the maternity wards of the medical schools, and in other ways have brought about beneficial improvements in the training and examination of undergraduates. They have persuaded the boards of management of hospitals to found in-patient maternity departments and to increase the number of maternity beds. Having, after years of opposition, brought into being the Central Midwives Board they have caused the training of midwives to be progressively raised from three months to half a year and then to a year. They have held united discussions, have published reports on obstetrical teaching and practice, and have urged many reforms. They have given evidence before committees and have, collectively and individually, written and suggested much concerning the creation of a maternity service and the prevention of maternal mortality. Last, and in future promise perhaps most important of all, they five years ago founded the British College of Obstetricians and Gynæcologists, whose first object is "to encourage the study and improve the practice of obstetrics and gynæcology." This corporate body, with every obstetric professor and specialist and teacher in Great Britain and Ireland and the Dominions a Fellow or a Member, and with a growing body of well-approved Diplomates, is already becoming a powerful influence in all that appertains to the obstetric service of this country.

The public health authorities also have been extremely active. The Notification of Births Acts and the Maternity and Child Welfare Act have been placed on the Statute Book. The local authorities and county councils have entered the obstetrical field with enthusiasm; welfare centres, antenatal clinics, the provision of hospital beds have arisen everywhere. Committees have been appointed to consider various aspects of the problem; there have been new regulations for the notification of puerperal pyrexia, and medical officers of health now inquire especially in all cases of death in childbirth. A notable series of reports has been issued by the Ministry of Health, whose late chief medical officer, Sir George Newman, has done everything humanly possible to put the facts before the medical and lay public and to awaken interest. This is a remarkable record of high endeavour. But it has had no effect on the maternal mortality-rate. Everything has in fact been done but the one essential thing. Imagine the British Admiralty sending a battleship into action with an improvised crew. But that is just what has been done in the battle which has been joined against the maternal mortality-rate. The necessary personnel has not been trained, and until this has been done there is not the slightest chance of victory. This is the theme to which I shall return again and again throughout this paper.

INFORMATION AT OUR DISPOSAL

A remarkable array of reliable information has during the past few years been gathered about the problem. The statistics of all countries and the manner in which they are computed are available, so that country can be compared with country. Reports, prepared by Government departments and by medical bodies, of the problem as it affects individual countries or large cities have been issued; whilst the number of monographs dealing with the problem in a general way or as regards its different components is immense. It would, in fact, be difficult to mention any medical problem which has been attacked in so thorough a manner. The knowledge at our disposal is ample; all we have to do is to make proper use of it. The two most impressive documents which have been issued lately are what may be called the Newman Report and the New York Report (the Report of the Departmental Committee of the Ministry of Health, interim (1930) and final (1932), under the chairmanship of Sir George Newman; and the report issued by the New York Academy of Medicine on "Maternal Mortality in New York City," 1933).

Both reports should be studied together; for both have many points in common. The New York report, not emanating from any government or official department, can afford to be, and is, very much more outspoken on the medical or professional aspects. Both reports have classified the deaths as "preventable" and "non-preventable." The Newman Report concludes that at least one-half of the maternal deaths are preventable, and states that had the information available been fuller this number would probably have been higher. The American Report confirms the latter statement; for the information available was more complete and the proportion of deaths regarded as preventable was as high as two-thirds. The following extracts are significant:—

> "We are, however, convinced, that the primary essential for the reduction of a high maternal mortality is sound midwifery, before, during and after childbirth, and this does not chiefly depend upon administrative arrangements or the expenditure of public money." (Newman Report, final, p. 134.)

---

[*] Read at a sessional meeting of the Royal Sanitary Institute on April 9th, 1935.

> ". . . at least half the deaths which have come under review could have been prevented had due forethought been exercised by the expectant mother and her attendant, a reasonable degree of skill been brought to bear upon the management of the case and adequate facilities for treatment been provided and utilised." (Newman Report, final, p. 134.)
>
> "The incapacity of the attendants, either in judgment or skill, contributed significantly to the large number of avoidable deaths. Their failure to provide proper prenatal care has already been pointed out. The prognosis of delivery was frequently incorrect. Labor was often improperly conducted. The physicians many times were apparently ignorant of indications and contra-indications for interference. Operative procedures were undertaken when there was no indication or plain contra-indication. Labor was terminated by rapid traumatizing delivery when non-interference was called for. Operative procedures were performed on potentially infected patients. Attendants were tardy in obtaining proper consultations. There was failure to treat severe complication with all the means which should have been available. Difficult obstetrical operations were performed by physicians whose training and experience could not be considered adequate." (New York Report, p. 215.)

Naturally enough, both reports created a considerable stir in their respective countries. The central theme which, thinly veiled in the British but naked in the American, runs through both reports is that the problem is first and foremost one of obstetric personnel. In other words, the main problem is one of assembling a properly trained corps of doctors and midwives and maternity nurses and of making their services available at the right times and in the right places, together with all the accompanying support of first-rate maternity hospitals.

MORTALITY STATISTICS AND DEATH CERTIFICATES

To what extent is a maintained or rising mortality figure due to correcting errors in death certificates? The Registrar-General bases his mortality statistics on death certificates and there is strong reason to believe that, so far as maternal mortality is concerned, death certificates sometimes fall grievously short of accuracy.

It is probable therefore that we need not attach too much significance to the *statistical rise* that has occurred in the mortality figure for 1933. For the rising figure may mean, not that every year a higher proportion of deaths occurs, but that the more careful scrutiny of death certificates is bringing into the category of maternal mortality deaths which in former years would have gone elsewhere. I believe the sieve is becoming finer and that in consequence we may have to face with equanimity similar or even higher figures for the next few years. It is a point worthy of consideration and much support is lent to it in recent publications. In the New York Report it was found that the percentage of error between the true cause of death and that given on the death certificates was no less than 18.

Exactly the same thing was found in the recent investigation into maternal mortality in Rochdale. When the investigators examined the case-records of 16 deaths which from the death certificates had been classed by the Registrar-General as due to some intercurrent disease ("associated" deaths), they found "seven cases in which there were serious obstetrical complications that could be regarded as factors of primary importance in leading to the death of the patient." They accordingly, for the purpose of their inquiry, transferred these seven cases from the class "associated" to the class "direct" deaths. Here was an error of no less than 44 per cent. in certification of the cause of death in childbirth, brought to light purely by chance. How prevalent is this sort of thing throughout the country? It has always seemed to me, from the ordinary routine of clinical experience, that the proportion of "associated" deaths to "direct" deaths was always ridiculously high as given by the Registrar-General (e.g., in 1933 it was 1 to 3·2). The public must be prepared for shocks if medical officers of health do their duty in this respect.

I will now deal with a few modern factors which impose an additional load on the ordinary hazards of childbirth and which clearly indicate that an improved maternity service is required even to keep the mortality-rate down to its present level.

ABORTION

The effect of including deaths from abortion in the maternal mortality figures must be clearly understood. The inclusion of abortions puts the maternal mortality-rate at the mercy of the abortionist. The death-rate from abortions is rising and the whole truth is not yet contained in the Registrar-General's figures. In 1926 the deaths from abortion formed 10·7 per cent. of the total maternal deaths, in the three years 1928 to 1930 they were 11·9 per cent., in 1932 they were 14·6 per cent. These figures, for some reason probably good, do not include coroners' cases. (If coroners' cases were included the above percentages would have to be increased by about one-sixth.)

From the preventive point of view deaths from abortion and deaths from childbirth are in a totally different category, and it would be helpful to a better understanding of the situation by the general public if they were kept separate by the Registrar-General.

How many of the abortion deaths occurred in the course of associated diseases, how many as the result of spontaneous abortion in healthy women, how many were "therapeutic" and how many were "illegal" abortions it is impossible to estimate. Certain facts are well enough known. One is that both "illegal" and "therapeutic" abortions are steadily increasing in number, and make an increasing contribution to the maternal mortality-rate. It is my impression that the number of unwanted pregnancies is much greater than it was, say, 20 years ago, because the contraceptive methods now in favour are less efficient than they were.

UNFAVOURABLE CHANGE IN METHODS OF OBSTETRIC PRACTICE

A striking change in the last 15 to 20 years is the remarkable widening of the indications for intervention during labour, and the great increase in the number of operative deliveries (induction of labour, forceps, and Cæsarean section). This has occurred in spite of the efforts to frustrate it on the part of leading teachers and text-books. It is interesting to speculate on the factors which have led to this, and I suggest that the following have been chiefly responsible: (*a*) the increasing employment of analgesics and anæsthetics which have by now become almost universal: in a certain proportion of cases these slow down labour and lengthen it, weaken the natural forces and so lead to an increase in the forceps-rate; (*b*) the building of hundreds of little cottage and other hospitals giving to local practitioners, who may possess neither the requisite judgment or skill, the opportunity of performing Cæsarean sections and other obstetric operations. The number of Cæsarean sections has increased in an astonishing manner.

In the Newman Report (final) 160 deaths after Cæsarean section were reported in the second series of

3805 deaths investigated. Many of these were after previous attempts at forceps delivery. The report states, with the characteristic courtesy and tact of official documents, "the Committee's observations lead them to believe that in some cases there may be a tendency to resort to Cæsarean section as treatment of complications of labour, perhaps without due consideration of other methods of obstetrical treatment." Exactly the same point was made by the late Whitridge Williams in the fifth edition (1923) of his text-book; after giving his opinion that the rising mortality of childbirth was to be explained on the supposition "that many practitioners in urban areas have been led astray by the teachings of those who regard labour as a pathological rather than a physiological process, with the result that interference upon insufficient indications is frequently undertaken by those who do not fully appreciate the risk involved," he goes on to state that an inquiry by a Committee of Massachusetts State Medical Society into the death-rate in that State during the year 1921 showed that, after puerperal infection, Cæsarean section was the most frequent cause of death. (*c*) Uninstructed antenatal work with its mistaken notions about "disproportion," "post-maturity," the "unengaged head," and the resort in consequence to unnecessary interference. (*d*) Any sort of interference with the course of normal pregnancy and labour, by meeting the demand of the patients for shorter labours, or by extension of the indications for drug or operative induction to suit the convenience of the patient, her friends, the doctor, the nurse. (*e*) An exaggerated idea of the value of the infant's life as compared with the life or health of the mother—due to the fact that nowadays pregnancies are spaced, regulated, and relatively rare. This interesting social change in reproductive method is exerting a great influence on obstetrical procedure.

ADVERSE FACTORS DUE TO CHANGING SOCIAL CIRCUMSTANCES

The additional load which these impose at the present time on the ordinary hazards of childbirth is probably not great; but they are slowly progressive. Amongst them may be mentioned: (1) a relative increase in primiparity, with restriction in the size of the family; (2) the increasing average age of all mothers, primiparæ and multiparæ; (3) the desire to limit the size of families must tend, *via* intentional abortion, to an increased maternal mortality-rate.

Two Aspects of the Problem of Lowering the Mortality

It seems to me that the problem of lowering the maternal mortality has two distinct aspects. The one is the lowering of the mortality in the so-called "black areas"; the other is the lowering of the mortality in the areas which may be called "favourable." The respective mortality-rates of these two are, as is well known, very different, and are set out for us clearly in the final Newman Report, the areas being placed in five groups. At the head of the favourable areas come the Home Counties with a mortality-rate of 3·4; at the foot of the black areas comes Wales with the figure of 5·9.

It is interesting to know what exactly would be the effect on the maternal mortality-rate for 1933 of bringing about a reduction of the rate for the "black areas," not down to the minimum figure of 3·4, but down to the fairly respectable figure of 3·9 for the group representing "Rural England, Southern and Eastern Counties." To do this it is requisite to know the number of deaths which occurred in the black areas, and Dr. Isabella Cameron has very kindly sent me the figures for four counties and twenty country boroughs in England, and ten counties and two country boroughs in Wales. The number of deaths was 715, and I have assumed a convenient mortality-rate of 5·9 for the whole group. (The calculation would of course be made accurately by anyone who had the complete figures for 1933 before him.) If the mortality-rate in these areas had been 3·9 instead of 5·9 the figure for the whole country would have been 4·1 instead of 4·5, representing a saving of the lives of 245 women. The calculation shows clearly that the effect of this degree of improvement in the "black areas" though most desirable would not be very remarkable, and would merely succeed in getting the mortality figures for the whole country back to the level of, say, twenty years ago.

LOWERING THE MORTALITY IN THE BLACK AREAS

It was always believed that this would be a fairly simple problem, but no one suspected how simple until its solution in Rochdale had been undertaken by the medical officers of health of that town (Dr. Andrew Topping and Dr. John Innes, his successor). The paper published in February last by Oxley, Phillips, and Young, entitled "Maternal Mortality in Rochdale, an achievement in a Black Area," was surely an astonishing obstetrical revelation. At the same time it was, I fear, a telling indictment of the local obstetric personnel. Rochdale for many years was in the unenviable position of having one of the highest maternal mortality-rates in England. During the three years 1929–1931 it was 10 per 1000. A study of the circumstances leading up to each death made it appear more than likely that a large proportion of the deaths had been due to too frequent intervention in the course of labour by the medical attendants. The problem was how to stop this. As far as the medical personnel was concerned there was not the least difficulty in getting their support, for as soon as the true state of affairs was brought to their notice the response was prompt and satisfactory, and the interest and support of doctors and midwives was at once enlisted. The second step was to awaken the interest of the community in general, and of the women in particular, in the medical facts. To effect this all available agencies, such as the pulpit, the platform, and the press, were used. The women thus were taught that, to safeguard themselves, they should make the fullest use of the antenatal clinics and should at once report at the first sign of any abnormality, and should refrain from attempting to persuade the doctor or the midwife to act contrary to their best judgment in hurrying the course of labour. The result was most remarkable. The "drive" was begun in 1931. For the three years 1932–1934 the maternal mortality of Rochdale had fallen from its reproachful figure of 10 per 1000 to a figure which was approximately the maternal mortality of the rest of the country—namely, to 3·9 per 1000. What was accomplished in Rochdale can be accomplished in similar centres. It is important to note the delightful simplicity of the methods employed. First and foremost there was no alteration in the personnel; there were the same doctors and the same midwives. There was merely on their part a change of spirit and a change of method. In the hospital it was particularly noticed that women with complications of labour were being sent in increasing numbers at a stage when the complication was capable of being treated with greater safety. In the second place it should be noted that the scheme itself, and the preliminary inquiries which led up to it, had its origin in the public health department of the borough, which was in the position to obtain the relevant facts, and to supply the administrative machinery required for the inception and development of the changes called for in the maternity services.

It is true that the Rochdale sample was only a small one, comprising about 1200 births per annum, and that the drop in the death-rate might be alternatively explained by the laws of chance or on the basis of natural variations in the incidence of disease occurring in groups of years. To me, however, all the circumstances of the case carry conviction.

I have described the Rochdale experiment at some length because it is an example of the simple problem of reducing the high mortality of the black areas down to a reasonably low level. Very different is the other aspect of the problem—namely, that of appreciably lowering the figure for the country as a whole, over and above what would be accomplished by cleaning up the black areas.

LOWERING THE MORTALITY IN THE FAVOURABLE AREAS

The problem of reducing the maternal mortality below the best figures for the country—namely, below the figures for the group of Home Counties or for London, or even of reducing it to the still lower figure for the Netherlands (i.e., just below 3 per 1000)—presents an entirely different problem. To reduce the mortality in the black areas was easy, and required no change of personnel and no additional expense. But to reduce the mortality to a figure below the existing best will be by no means easy and will require a very great effort. It can only be brought about by a radical change of personnel—of doctors and midwives both. This to my mind is the key to the whole problem of lowering maternal mortality. A personnel cannot be improvised, but must be trained. Before it can be trained the requisite training schools must be built and staffed. The whole process will take time and the country must be asked to wait patiently until the standard of midwifery practice has been remarkably raised and is undertaken by a select corps of men and women, based on high-class obstetric institutions. In Munro Kerr's words, "Holland's death-rate is low primarily because of the excellence of its obstetric service" (or, he might have written "of its obstetric *personnel*"). "Good physique, a simple and better dietary, absence of rickets, all play a part; but they are only influencing factors."

The problem of maternal mortality, let me repeat, is not obscure; and a considerable reduction in the present rate will not be difficult once the proper personnel, with the requisite training centres, have come into being and a new obstetric tradition has arisen—as in such circumstances it surely will. The great mistake that the central and local authorities of this country have made is in believing that the creation of an efficient obstetric service was chiefly an administrative problem.

A discussion of the administrative problem of who is to pay for establishing a network of obstetric training centres of university standard throughout the country, and for running them, is outside my province. Moreover, a discussion of details about methods of teaching and training the requisite personnel are beyond the scope of this paper. The most complete and up-to-date discussion of the whole subject, with references to recent reports and other literature, is to be found in Munro Kerr's splendid book on "Maternal Mortality and Morbidity."

It must be clearly recognised that practical training in obstetrics must come after graduation, and the proposed training centres would be used for post-graduates who, as residents for a period, would learn the work under recognised teachers. At the present time the necessary hospitals and teaching organisation for giving post-graduate training are (apart from the few resident posts available in maternity hospitals or in maternity departments of some general hospitals) almost non-existent in this country. The teaching of undergraduates is best done, as at present, at general hospitals with attached medical schools at most of which the instruction is now adequate. All undergraduates must be taught the principles of obstetrics. But the teaching of obstetrics as a practical art and craft, how to deal with complications and how and when to perform operations, should be reserved for doctors who after graduation decide to "take up obstetrics" and to devote further study to it. A sufficient period of responsible resident work in contact with high standards of practice and teaching will lead to the acquisition not only of skill and good judgment but also of what may be called an "obstetric conscience." Once an "obstetric conscience" has been acquired a doctor is proof against any amount of temptation to hurry or to interfere unnecessarily, or to offend in any other way against the cardinal principle of preservation of normality. All such obstetric practitioners (the majority of whom will probably be in general practice) would no doubt receive professional recognition in the form of a special diploma. They would gradually infiltrate the profession and come to be recognised and accepted by the lay public and by their colleagues.

There is nothing new in the foregoing proposal for the principle of a trained personnel. It has been reiterated many times by the obstetric branch of the profession, individually and collectively, from the 1919 "Report on the Teaching of Obstetrics" of the Obstetrical Section of the Royal Society of Medicine onwards. Anyone who cares may read this and subsequent reports, books, and monographs. I have not quite lost my illusions that something sensible will be done in this respect for the women of this country; but there is evidently a deal of vested interest and of jealously vested authority to be overcome. Why not make the maternity service a national service with centralised powers? The present conditions cannot be allowed to continue.

Medical Society of Individual Psyc logy.—Owing to illness Dr. Adler will be unable o deliver the lecture to this society on May 2nd, which was nounced in our issue of April 6th.

Eyesight Testing in South Africa.—Q South African correspondent writes: Under a propose mendment to the Medical, Dental, and Pharmac ct of 1928, statutory qualification will be require all makers of spectacles in the Union; apart fr established practitioners, only those who have p an examination will be allowed to pursue this calling. R stra-tions will take place through the Medical Council, but the opticians will be represented on the Board charged with this duty. The question has arisen whether spectacle-makers should be allowed to use instruments such as the retinoscope and ophthalmoscope, and it is maintained by the trade that there is no danger attached to the use of such appliances by properly trained opticians. Diagnosis by spectacle-makers, and the use of drugs such as belladonna, are, however, to be strictly banned. Such terms as "optologist," "eyesight specialist," and "ophthalmic optician" are to be forbidden under the new law.

CONTINUOUS DRIP BLOOD TRANSFUSION

WITH CASE RECORDS OF VERY LARGE TRANSFUSIONS

By H. L. Marriott, M.D., M.R.C.P. Lond.
RESIDENT MEDICAL OFFICER, THE MIDDLESEX HOSPITAL, LONDON; ASSISTANT PHYSICIAN, THE MILLER HOSPITAL, GREENWICH; AND

A. Kekwick, M.B. Camb.
HOUSE PHYSICIAN, THE MIDDLESEX HOSPITAL

The continuous drip method of giving saline and other solutions intravenously is recognised as a therapeutic measure of the greatest value. Its great merit is that it allows large amounts of fluid to be introduced into the circulation very slowly and under perfect control. As far as we can discover, however, the drip device has not hitherto been applied to the prolonged continuous introduction of large quantities of blood, and we believe that there is considerable scope for this form of transfusion. The principal purpose of this paper is to describe a technique which has worked efficiently and easily. We are able to incorporate an account of cases, including transfusions, which appear to be much larger and more prolonged than any on record, and the paper concludes with a discussion of indications for continuous drip transfusion.

For the administration of large quantities of blood it is obvious that more than one donor is required. In one of our cases ten donors contributed together 5620 c.cm. of blood. The donors should all be compatible with the recipient (though not necessarily of the same group) and must be of the same group as one another, or agglutination will occur when their bloods are mixed in the reservoir. The assembly of numerous donors is easy if properly organised. We have found it convenient to bleed our donors in pairs at 8 A.M. and 8 P.M., during the progress of a continuous transfusion. In the 17 cases we have done, 100 donors were used, and only 7 of them were from the British Red Cross Society's Blood Transfusion Service, as it was felt that every effort must be made to use relatives and friends of the recipients before falling back upon the donors of this remarkable and most valuable Service. The amounts taken varied from 200 to 900 c.cm., according to their age, weight, sex, and physical condition.

Technique

It is in our opinion important that the blood should be collected by a closed method, so that it is not exposed at all to the risk of infection. We have used a special method which may be described later in a separate communication. It is desirable also to be certain of obtaining the full contribution decided upon as being correct for any given donor, and not be obliged to take less through difficulties in withdrawing the blood.

The principal difficulty in the use of citrated blood or drip transfusion, as compared with saline, is that the corpuscles tend to sediment in the reservoir and block the drip bulb. Some method of continuous, aseptic stirring of the blood is therefore necessary. We have achieved this by bubbling a continuous stream of filtered oxygen through the blood.

APPARATUS FOR DRIP TRANSFUSION (FIG. 1)

1. An oxygen cylinder fitted with a pressure regulator and fine adjustment tap.
2. Five feet of rubber tubing, interspersed with three filters, which connects the cylinder to
3. A glass reservoir of 4-pint capacity fitted with a rubber bung with two perforations through which project glass tubes. To one of these tubes is attached the tube from the oxygen cylinder, and, on the under side of the bung, a rubber tube which reaches to the bottom of the reservoir. To the other tube is connected a short piece of tubing and a filter—it serves as an outlet for the oxygen. The base of the reservoir is fitted with a circular gauze filter made of 28 gauge pure nickel wire, with 20 meshes to the inch, which serves to strain off any clots. The reservoir fits into a tin hanger.

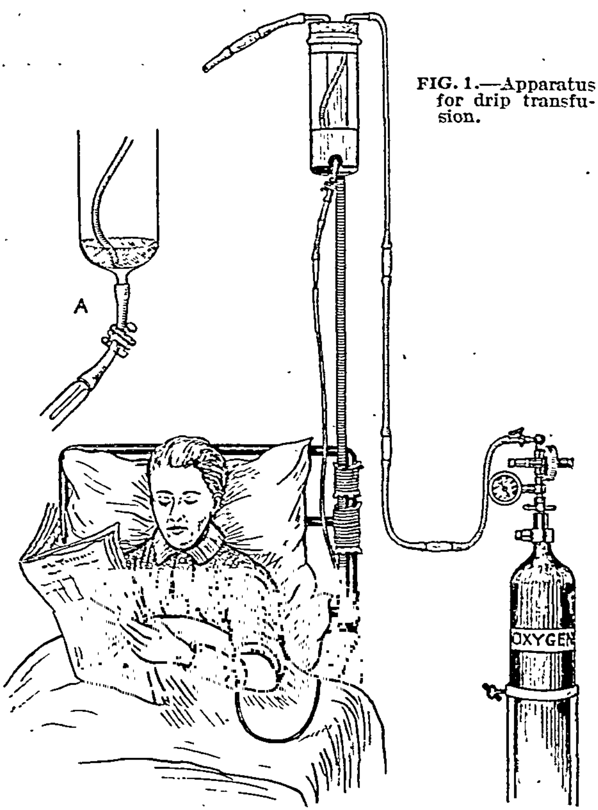

FIG. 1.—Apparatus for drip transfusion.

4. Four inches of rubber tubing (*not* pressure tubing), fitted with an adjustable screw clip, which connects the reservoir to—
5. A Laurie glass drip bulb (Fig. 2) joined to—
6. Seven feet of *pressure* tubing of 5 mm. external diameter (aspirating tubing) attached to—
7. A cannula of special device (Fig. 3) which can be tied into a vein firmly without kinking it. It is made of glass in various sizes and costs a few pence.

FIG. 2.—Laurie glass drip bulb.

FIG. 3.—Cannula of special design.

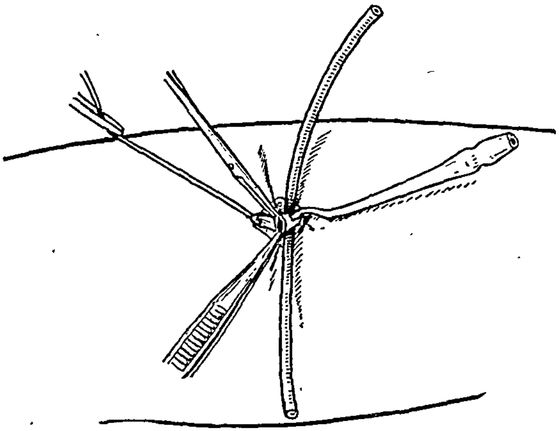
All the items of apparatus except No. 1 require sterilising, and may conveniently be baked together in a dressing tin along with the forceps, &c., mentioned later.

The first and most important step is selection of a vein in the arm or leg of the patient. Our choice has been, if possible, one of the veins in the middle of the forearm at a spot an inch distal to where it joins another vein, and with a valve at the junction which may be tested for by emptying the vein from above. Such a valve is useful in preventing reflux flow into the cannula which may occur under certain cir[illegible]stances. The middle of the forearm, rather th[illegible] bend of the elbow, is most desirable beca[illegible] of the elbow does not then compress the cannula against the vein wall and so obstruct the flow. There is no need for splinting, and the patient can flex his elbow as he wishes. The elbow flexure veins are the most inconvenient of all.

The reservoir with tubing connected is fixed at least 3 feet above the vein. A greater height is preferable as ensuring less variations in flow. An adjustable stand is a great convenience. The screw clip is left wide open. Care is taken to preserve the sterility of the outside of the distal 3 feet of pressure tubing which should rest upon a sterile towel. A pair of sterile Spencer Wells forceps is manipulated through the towel and clipped on to the tubing about a foot from the cannula.

It is convenient to introduce the cannula into the vein and start the drip flowing using saline rather than blood, and the next step is removal of the bung of the reservoir and introduction of enough sterile normal saline to cover the nickel gauze to a depth of half an inch (about 100 c.cm.). The Spencer Wells is again manipulated through the towel and temporarily released to allow enough saline to run through the tubing to expel the air in it. Air, of course, permanently remains in the upper part of the drip-bulb which is an air-lock. The forceps is reapplied after the minimum waste of saline.

Finally, before scrubbing up, the operator cleans the recipient's arm with spirit and applies a sphygmomanometer cuff and blows it up to a pressure sufficient to obstruct the venous flow and so render the selected vein prominent. He then sterilises himself and puts on a sterile gown and gloves. A small amount of 1 per cent. novocain is injected intradermally, and an incision made through the skin over the vein *transversely* to it and not more than 2 mm. longer than the breadth of the vein. The vessel is displayed by blunt dissection with forceps, and freed and presented into the wound, being there maintained by passing under it a piece of fine rubber tubing (Fig. 4). The distal end of the vein is ligatured, the ends of the ligature being left long, and another ligature is tied very loosely around the proximal end and clipped. The tourniquet is now deflated—a point very easily forgotten.



IG. 4.—Showing the vessel maintained by a piece of fine rubber tubing.

The vein is cut half across with scissors and the lumen displayed, showing the shining intima. Any bleeding is controlled by traction on the loose ligature. The tip of one blade of a pair of fine Spencer Wells forceps (spider forceps) is introduced into the right-hand (operator's right hand) side of the vessel and the forceps clipped on and left exerting gentle traction by its weight. With a pair of dissecting forceps in his left hand the operator grasps the left-hand wall of the vein and opens up the lumen while with his right hand he slips in the cannula (Fig. 4). The loose proximal ligature is tied behind the bulbous tip of the cannula. The Spencer Wells occluding the pressure tubing is released momentarily, being reapplied as soon as a satisfactory flow in the drip bulb is observed. A second ligature is passed and tied around the cannula which should only enter the vein up to the shoulder of its bend; this ligature is for safety and duplicates the proximal one already tied. The rubber tube under the vein is removed and the tiny wound should fit closely round the cannula.

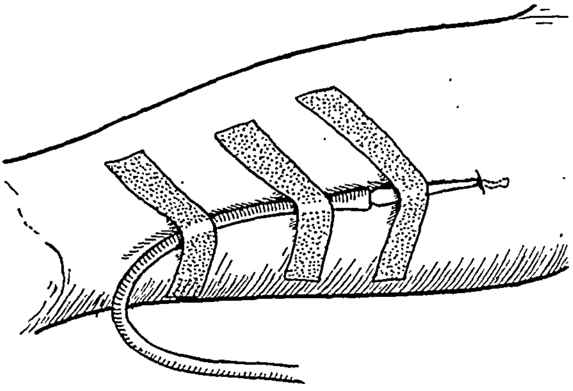


FIG. 5.—Showing the cannula and tubing fixed to the forearm by strips of strapping.

By means of strips of strapping the cannula and tubing are fixed to the forearm (Fig. 5). The long ends of the distal ligature are also tied round the cannula. Next the patient's arm is flexed slowly so that the operator can assure himself that even full flexion at the elbow does not obstruct the flow in the drip bulb, the Spencer Wells again being momentarily released and reapplied. If there is any obstruction, the elbow bend must be padded sufficiently to restrain the obstructive degree of flexion. Sterile gauze and wool is placed over the cannula and strapped tubing, and the whole bandaged up to the elbow, firmly below the cannula and *lightly above so that the vein is not compressed.* The operator may now cease to keep himself sterile.

The next procedure is to start and control the flow of oxygen in the reservoir. The bubbles can be observed in the saline by looking up from underneath at the base of the reservoir. About 60–120 bubbles per minute will keep the blood adequately stirred. A faster rate results in troublesome frothing. At this rate of flow the oxygen consumption is so small that the pointer of the cylinder's pressure gauge hardly moves at all in 24 hours. The oxygen has the minor merit of delivering the blood in an oxygenated condition.

Blood is now introduced into the reservoir by removing the bung and pouring it in. Up to 1500 c.cm. may be conveniently introduced, leaving enough space above it for froth. During the introduction there should be the minimum exposure of the blood, and care must be taken to avoid droplet infection by not breathing or speaking over it.

The flow of blood is now started by removing the Spencer Wells forceps. As the screw clip is still wide open the blood will be seen to flow in a rapid stream through the drip bulb. The screw is adjusted till the desired rate of flow is obtained. A flow of a litre in x hours is roughly obtained by a flow of $280/x$ drops per minute. A convenient rate of flow for many purposes is 40 drops per minute = a litre in 7 hours or a pint in 4 hours. The dripping will, however, be found to be subject to slight variations and the nurse should be instructed to inspect it at least half-hourly and to adjust it as may be required. She should also keep an eye on the froth above the blood; about 2 inches to 3 inches of froth indicates a satisfactory rate of oxygen bubbling.

Apart from these minor occasional adjustments, there is no further need to touch any part of the apparatus beyond periodically replenishing the reservoir with blood. Moreover the pressure tubing is so long that the patient can do what he likes. He may use his arm freely, turn over in bed, and sleep in any position he desires. The absence of a splint and the free mobility of the arm cause the patient to be untroubled by, and indeed oblivious of, the presence of the cannula in his forearm.

It is very important indeed that the citrate and saline solutions used shall be prepared from distilled water entirely free from dead organisms. Otherwise troublesome rigors are inevitable.[1, 2]

Case Records

We have now performed 17 large drip transfusions. It is realised that were this paper an attempt to assess the value of the method, 17 cases would not be enough. That is not its purpose, which is to describe a technique which is not only practicable but easy. This we feel confident in doing, since in the 17 cases we met with no technical hitch whatever in the transfusion of 71,390 c.cm. of citrated blood (60,710 c.cm. of blood plus 10,680 c.cm. of citrate solution), or over 15 gallons. The total time taken was 537½ hours.

The largest transfusion was 5620 c.cm. of blood plus 1000 c.cm. of citrate solution; the smallest was 2200 c.cm. of blood plus 400 c.cm. of citrate solution. The strength of citrate solution used was 3·8 per cent. in every case. The average rate of delivery of citrated blood to the patients worked out at 133 c.cm. per hour, or a litre in 7½ hours. Four of the cases are recorded below as illustrations of the possibilities of the drip transfusion of large quantities of blood. We have picked them out from the rest as in each one it appeared that the transfusion was unquestionably life-saving.

CASE 1 (No. 69786. Under care of Dr. C. E. Lakin).—The patient was a male, aged 27, suffering from severe ulcerative colitis, who had been ill for six weeks. His general condition was extremely poor and he was running a swinging temperature touching 103° F. in the evenings, and with a pulse-rate ranging around 130. Ordinary therapeutic measures had failed to arrest his downward progress and a fatal issue appeared imminent. The hæmoglobin percentage estimated immediately before commencements of the drip transfusion was 35.

Drip transfusion was maintained for 27 hours, during which 3400 c.cm. of blood and 700 c.cm. of citrate solution (total of 4100 c.cm., or just over seven pints) was introduced. Hæmoglobin estimations were carried out at intervals, and at the end of the transfusion his hæmoglobin was 98 per cent. The improvement effected in his general condition was remarkable. His complexion turned from extreme pallor to a rosy flush. His demeanour changed from that of a dying man to an optimistic invalid. His temperature dropped to normal and there was no more blood in his stools up to the time of his discharge from hospital.

CASE 2 (No. 69543. Under care of Dr. R. A. Young).—A male, aged 57, suffering from severe hæmatemesis and melæna of uncertain causation, but thought to be probably due to gastric ulcer. When drip transfusion was decided upon he had been in the hospital for five days and was rapidly getting worse and continuing to lose blood. His condition appeared desperate, and his hæmoglobin was reduced to 25 per cent.

Drip transfusion was carried out at an even slower rate than in the former case, and 47 hours were taken to administer 4100 c.cm. of blood and 800 c.cm. of citrate solution (total of 4900 c.cm., or 8½ pints). The patient slept during most of the time without sedatives. At the conclusion his hæmoglobin had risen to 103 per cent. and his complexion was positively ruddy. He expressed himself as feeling almost well, and read a newspaper with interest. His blood pressure was taken at intervals and slowly rose from 110/60 at the commencement to 150/75 at the end. In spite of this rise he had no more bleeding and made a smooth recovery.

CASE 3 (No. 70148. Under care of Mr. R. Vaughan Hudson).—A man, aged 37, known to have a large duodenal ulcer, admitted suffering from severe melæna. When we started drip transfusion he had been bleeding for five days. His hæmoglobin was 30 per cent. Mr. Vaughan Hudson considered that his condition was such as to make operation then quite unjustifiable.

Forty hours were taken in transfusing 4600 c.cm. of blood and 800 c.cm. of citrate solution (total of 5400 c.cm., or 9½ pints). His hæmoglobin rose to 105 per cent. and he felt and looked enormously improved. Operation disclosed a duodenal ulcer the size of half a crown, whose base was partly formed by the gall-bladder and pancreas. Partial gastrectomy was performed and the first part of the duodenum removed with part of the ulcer. At the end of the operation the patient's pulse-rate was 84. He made an uninterrupted recovery.

CASE 4 (No. 58259. Under care of Dr. G. E. S. Ward).—The case of this woman is of peculiar interest in regard to the pathology of her condition, and it is being independently reported and discussed. She was suffering from very severe hæmolytic anæmia, thought to be of the acholuric jaundice type. She showed a marked reticulocytosis combined with progressive anæmia. It was considered that splenectomy offered the only hope, but was out of the question on account of her very poor condition.

When drip transfusion was started her hæmoglobin was 20 per cent. During 51½ hours a total of 5620 c.cm. of blood plus 1000 c.cm. of citrate was transfused. At the end of this time her hæmoglobin had risen to 88 per cent. In our opinion the rise of only 68 per cent. indicated severe blood destruction, as from our experience in other cases we would have expected a rise of 90 to 100 per cent. Splenectomy was performed by Mr. Pearce Gould. The patient has made a complete recovery.

The four cases recorded have been deliberately sketched in the merest outline as the purpose of this paper is only to describe a technique. They serve merely as illustrations of what can be done in the way of transfusion of large amounts of blood over a long time. In all our cases repeated observations of numerous clinical, hæmatological, and biochemical facts have been made, and when there are enough of them it will be possible to draw conclusions. Meanwhile the practicability of the technique seems of sufficient importance to warrant a preliminary communication in the hope that others will investigate its potentialities.

Our experience has shown that in order to carry out drip transfusion with a proper regard to the recording of data, it is wise to have a printed case-sheet or form, itemising in an orderly manner the necessary observations, with blank spaces left for filling them in. Such a case-sheet saves much mental wear and tear. We have constructed one as a printed quarto double sheet and shall be pleased to supply copies.

Possible Indications

We believe that the method which has been described, or one similar in principle, will be found to have important applications in the treatment of both medical and surgical conditions. It is our conviction that blood transfusion is to-day exploited only to a very small extent of its potentiality, because it is still being employed in homœopathic doses. There is far from general realisation of the fact that a transfusion of 500 c.cm. to an adult does no more than augment his hæmoglobin by some 8 to 10 per cent. of its normal value. It is the more surprising that this valuable method of treatment is so feebly used when blood is easily and freely available everywhere.

The drip method is firstly essentially for *large* transfusions, but it is necessary to point out that what is or is not a large transfusion depends mainly upon the size of the patient. Thus a transfusion of a litre in an adult of 11 st. is roughly paralleled by a transfusion of 46 c.cm. to a baby of 7 lb. A transfusion, for the purposes of this discussion, may arbitrarily but serviceably be defined as "large" if it exceeds 5 c.cm. per pound of the recipient's body-weight.

The second essential characteristic of the drip method is that it is for *slow*, controlled transfusions. It enables the blood to be introduced over many hours or several days. The normal blood volume is approximately one-eleventh of the body-weight, or 5 to 6 litres in an adult.[3] In transfusing for anæmic states it is possible to calculate very roughly the amount of blood required, from the deficiency of the hæmoglobin below an ideal of 100 per cent., allowing 500 c.cm. of blood for each 9 per cent. of deficiency. We employed this method in our cases and generally found the practical result to work out accurately with the theoretical prediction.

It is proposed to limit discussion to the possible scope of drip transfusion in the several groups of anæmic states.

According to Price-Jones [4] the normal red cell count is from 4½ to 6½ millions per c.mm. in males, and from 4 to 6 millions in females. The normal range of hæmoglobin percentage is from 95 to 117 and from 85 to 111 in the respective sexes. Anæmia exists when the figures are below the lower normal limits. Modern classification of the anæmias rests upon the simple idea that a patient is anæmic either because he is not making enough red cells or because they are being lost or destroyed too fast. Deficient formation on the one hand and excessive loss or destruction on the other are the primary categories.

HÆMOPOIETIC ANÆMIAS

The anæmias due to deficient formation of red cells all intimately concern the bone-marrow, which is the factory of their origin. Diminished output of red cells from the bone-marrow is due either to depression —either non-specific or specific—of its blood-forming function, or to a normally active marrow being, in one way or another, deprived of the raw materials essential for hæmopoiesis.

Anæmia due to non-specific depression of the bone-marrow occurs in many diseases accompanied by general toxæmia. The activity of the bone-marrow is depressed along with the activity of all the other organs. Examples of such diseases are chronic sepsis, many fevers, and cancer. The conditions which may give rise to anæmia in this way are so numerous that they form, necessarily, a large group of the anæmic states. In all of them the patient is in a vicious circle of which the anæmia forms an important part. It would surely seem that in all cases in which the patient's life is in jeopardy, and which are not due to an essentially hopeless cause, great benefit might accrue from a drip transfusion designed to raise the patient's hæmoglobin to 100 per cent. and so break the vicious circle at at least one point. We have had a very good result in a severe case of puerperal sepsis whose hæmoglobin was down to 52 per cent.

Another very important indication for drip transfusion in this class of anæmia might be found in severely anæmic cases for whose cure a serious surgical operation is necessary—e.g., for the eradication of some extensive focus of septic infection or the removal of a growth. Restoration of the blood to normal as a pre-operative measure might conceivably mean all the difference between life and death. We have transfused several such cases.

The anæmias due to specific depression of the bone-marrow do not form a large group. There are first of all those due to injury to the marrow by a known agent such as lead, bismuth, benzol, arsphenamine, the rays of radium, and X rays—the secondary aplastic anæmias. Then there are those due to supposed depression of the marrow by an unknown agent—the primary aplastic anæmias. Whatever the cause, in severe aplastic anæmia there is no doubt but that at present blood transfusion is the only method of keeping the patient alive. There are recorded cases in which particular patients have been kept alive by an enormous number of repeated transfusions. For this type of case drip transfusion would seem the easiest and most efficient method of blood restoration. The patient might once a month have a drip transfusion for 24 hours restoring his hæmoglobin to 100 to 120 per cent. In this way, the lives and careers of individuals of value to the community might be perpetuated in a state of normal efficiency by the coöperation of a small phalanx of regular donors (say each giving his blood every quarter).

The important group of anæmias due to deprivation of the marrow of raw materials necessary to hæmopoiesis have been much studied and elucidated in the last decade. They will be found fully described and classified in monographs devoted to the subject. The main members of the group in this country are the iron-deficiency anæmias, especially nutritional anæmia of infants and achlorhydric microcytic anæmia of adults, and the hæmatinic factor deficiency anæmias of which pernicious anæmia is the great example. The results attained by liberally supplying the deficient hæmopoietic factors are so brilliant that large transfusions could only be indicated in very special circumstances. Such circumstances might be found when the patient's life is imperilled by some complicating acute infection, or when an urgent and severe surgical operation is necessary, or in a pregnant woman very near term. Under such conditions, drip transfusion might seem the ideal method of relatively quickly restoring the blood to normal and tiding over the emergency till the slower process of normal blood regeneration be satisfactorily established.

LOSS OR DESTRUCTION OF RED CELLS

The second main subdivision of the anæmic states concerns the anæmias due to excessive loss or destruction of red cells. Loss is due to bleeding, and, of course, the anæmias due to hæmorrhage are the most important group of all. Destruction is due to hæmolysis from various causes. The hæmolytic anæmias form a numerically much less important group.

In the immediate relief of anæmia due to acute bleeding, drip transfusion is not indicated, as the loss of blood volume does not preclude, but indeed calls for, relatively rapid transfusion. The only exception to this statement is that the drip method may be the most convenient for use when bleeding is very prolonged, because of its automatic and readily controlled nature. An example of such use was seen in our third case—a very extensive cranial operation. The drip was left running the whole time and required no handling beyond occasional adjustments of flow as the hæmorrhage fluctuated; in all 2700 c.cm. of blood was transfused. Although the drip may be run so slowly that a day may be taken to administer a pint, yet when occasion demands it may be speeded up to its full rate of a pint in three minutes. During the above case it was left running unattended while fresh donors were bled.

In anæmia due to subacute or chronic bleeding the indications for drip transfusion might be conditioned by a variety of circumstances. Thus in severe anæmia due to a readily arrested source of bleeding, such as piles, there seems to be no need for transfusion unless the patient's life is jeopardised by some complicating infection. On the other hand, in severe anæmia due to hæmorrhage whose arrest necessitates a major operation, drip transfusion would have one of its chief functions. The high mortality in recurrent hæmatemesis and melæna from peptic ulcer is well known, and the dilemma of having to choose between hoping the bleeding will stop in the morphinised patient, or operating to arrest it, too often results in death whatever the choice made. There seems no doubt that in such cases surgery would be the method of election if it could be made safe by preliminary relief of the exsanguination. Drip transfusion can achieve this aim and the patient be delivered to the surgeon with 100 per cent. hæmoglobin and accompanied to the theatre with the drip still running. We have done this in two cases. Again, in a severe operation, such as Wertheim's hysterectomy, the mortality is unquestionably higher when operation is performed on an already anæmic patient. Twenty-four hours delay for drip transfusion of several pints of blood might surely lower the death-rate figures in such cases.

The hæmolytic anæmias are a small group in this country, but in such conditions it is imaginable that drip transfusion might be a powerful therapeutic weapon, especially if the patient's life be menaced by urgent complications.

Discussion has been limited to the possibilities of continuous drip blood transfusion in the treatment of the anæmic states where the indications appear fairly clear. We are not unmindful, however, that the method might have value in conditions not essentially characterised by anæmia. Brilliant results from blood transfusion of the ordinary type have been recorded in almost every conceivable condition. It may be that in a not negligible fraction of these, cure was rightly ascribed to transfusion, and that failure of consistent confirmation of beneficial results has been due to under-dosage.

We wish to express our warm thanks to the members of the honorary staff of the Middlesex Hospital who have kindly allowed us to transfuse their cases and accorded permission to publish our results. We are indebted to the staffs of the Bland-Sutton institute of pathology and Courtauld institute of biochemistry for carrying out special investigations, and to our illustrator, Mr. S. A. Sewell, for his help. Without the extremely willing coöperation at all hours of the sister and staff of the main theatre this work could not have been done.

SOME PROBLEMS OF INFLAMMATION RELATED TO SURGERY[*]

By Valy Menkin, M.D. Harvard
INSTRUCTOR IN PATHOLOGY, HARVARD UNIVERSITY MEDICAL SCHOOL, BOSTON, MASS.

THE fundamental mechanisms of inflammation are obviously of great interest to the surgeon. His constant contacts and the necessity of handling various types of pyogenic infections require on his part an intimate knowledge of the inflammatory reaction in all its known manifestations. I propose to discuss here some information gathered for the past few years concerning the relationship of inflammation to immunity.

Inflammation, broadly defined, is the complex vascular, lymphatic, and general tissue response to the presence of an irritant. The development of the inflammatory reaction consists of a series of dynamic and sequential changes which tend to localise and ultimately dispose of this irritant. It is with a study of some of these changes that we have been engaged.

Several years ago it was found that when a vital dye, trypan-blue, is injected directly into the subcutaneous tissues of a rabbit, the dye rapidly diffuses into the tributary lymphatics, so that if these regional vessels are cannulated, the lymph is stained intensely with the dye. If, on the other hand, the same dye is injected into a prepared area of inflammation induced by a chemical irritant such as aleuronat, the dye fails to penetrate to either the draining lymphatic vessels or the regional lymph node. The dye has evidently been fixed in the inflamed area. Furthermore, it was observed that there is an important time-relationship in this connexion.[1] The dye was found fixed as early as 30 minutes after the subcutaneous injection of aleuronat as an irritant. I shall refer to this fact later on and the importance of this early retention of foreign substances at the site of an acute inflammation will be pointed out. Subsequent experiments showed that intravenous injection of this dye is followed by a rapid accumulation of trypan-blue in the inflamed focus. Studies revealed that this accumulation is in part due to the increased capillary permeability in inflammation and also, as just pointed out, to the inability of the dye to drain outward into the regional lymphatics.

The extent of increased plasma filtration due to capillary injury and increased capillary pressure at a point of injury is open to quantitative measurements.[2] By means of a colloidal dye, it was shown that with certain inflammatory irritants the normal permeability of capillaries is increased about two-fold. Particulate matter which is unable to pass through the normal capillary endothelium readily passes through the lining of such channels in an inflamed area.[3]

These findings are applicable to micro-organisms. When bacteria, as *B. prodigiosus* or *B. pyocyaneus*, are injected into the circulating blood stream they localise and are recovered from foci of inflammation in greater numbers than from surrounding normal tissues. This was found by culturing inflamed skin areas and by comparing the number of colonies obtained with those recovered from corresponding normal cutaneous regions. Bacteria when injected directly into an area of injury are likewise fixed to have important applications in the treatment of both medical and surgical conditions. It is our conviction that blood transfusion is to-day exploited only to a very small extent of its potentiality, because it is still being employed in homœopathic doses. There is far from general realisation of the fact that a transfusion of 500 c.cm. to an adult does no more than augment his hæmoglobin by some 8 to 10 per cent. of its normal value. It is the more surprising that this valuable method of treatment is so feebly used when blood is easily and freely available everywhere.

---

[*] Read before the clinical congress of the American College of Surgeons, Boston, Oct. 16th, 1934.

The drip method is firstly essentially for *large* transfusions, but it is necessary to point out that what is or is not a large transfusion depends mainly upon the size of the patient. Thus a transfusion of a litre in an adult of 11 st. is roughly paralleled by a transfusiou of 46 c.cm. to a baby of 7 lb. A transfusion, for the purposes of this discussion, may arbitrarily but serviceably be defined as "large" if it exceeds 5 c.cm. per pound of the recipient's body-weight.

The second essential characteristic of the drip method is that it is for *slow*, controlled transfusions. It enables the blood to be introduced over many hours or several days. The normal blood volume is approximately one-eleventh of the body-weight, or 5 to 6 litres in an adult.[3] In transfusing for anæmic states it is possible to calculate very roughly the amount of blood required, from the deficiency of the hæmoglobin below an ideal of 100 per cent., allowing 500 c.cm. of blood for each 9 per cent. of deficiency. We employed this method in our cases and generally found the practical result to work out accurately with the theoretical prediction.

It is proposed to limit discussion to the possible scope of drip transfusion in the several groups of anæmic states.

According to Price-Jones [4] the normal red cell count is from 4½ to 6½ millions per c.mm. in males, and from 4 to 6 millions in females. The normal range of hæmoglobin percentage is from 95 to 117 and from 85 to 111 in the respective sexes. Anæmia exists when the figures are below the lower normal limits. Modern classification of the anæmias rests upon the simple idea that a patient is anæmic either because he is not making enough red cells or because they are being lost or destroyed too fast. Deficient formation on the one hand and excessive loss or destruction on the other are the primary categories.

HÆMOPOIETIC ANÆMIAS

The anæmias due to deficient formation of red cells all intimately concern the bone-marrow, which is the factory of their origin. Diminished output of red cells from the bone-marrow is due either to depression —either non-specific or specific—of its blood-forming function, or to a normally active marrow being, in one way or another, deprived of the raw materials essential for hæmopoiesis.

Anæmia due to non-specific depression of the bone-marrow occurs in many diseases accompanied by general toxæmia. The activity of the bone-marrow is depressed along with the activity of all the other organs. Examples of such diseases are chronic sepsis, many fevers, and cancer. The conditions which may give rise to anæmia in this way are so numerous that they form, necessarily, a large group of the anæmic states. SOME PROBLEMS OF INFLAMMATION RELATED TO SURGERY[*]

By Valy Menkin, M.D. Harvard

INSTRUCTOR IN PATHOLOGY, HARVARD UNIVERSITY MEDICAL SCHOOL, BOSTON, MASS.

The fundamental mechanisms of inflammation are obviously of great interest to the surgeon. His constant contacts and the necessity of handling various types of pyogenic infections require on his part an intimate knowledge of the inflammatory reaction in all its known manifestations. I propose to discuss here some information gathered for the past few years concerning the relationship of inflammation to immunity.

Inflammation, broadly defined, is the complex vascular, lymphatic, and general tissue response to the presence of an irritant. The development of the inflammatory reaction consists of a series of dynamic and sequential changes which tend to localise and ultimately dispose of this irritant. It is with a study of some of these changes that we have been engaged.

Several years ago it was found that when a vital dye, trypan-blue, is injected directly into the subcutaneous tissues of a rabbit, the dye rapidly diffuses into the tributary lymphatics, so that if these regional vessels are cannulated, the lymph is stained intensely with the dye. If, on the other hand, the same dye is injected into a prepared area of inflammation induced by a chemical irritant such as aleuronat, the dye fails to penetrate to either the draining lymphatic vessels or the regional lymph node. The dye has evidently been fixed in the inflamed area. Furthermore, it was observed that there is an important time-relationship in this connexion.[1] The dye was found fixed as early as 30 minutes after the subcutaneous injection of aleuronat as an irritant. I shall refer to this fact later on and the importance of this early retention of foreign substances at the site of an acute inflammation will be pointed out. Subsequent experiments showed that intravenous injection of this dye is followed by a rapid accumulation of trypan-blue in the inflamed focus. Studies revealed that this accumulation is in part due to the increased capillary permeability in inflammation and also, as just pointed out, to the inability of the dye to drain outward into the regional lymphatics.

The extent of increased plasma filtration due to capillary injury and increased capillary pressure at a point of injury is open to quantitative measurements.[2] By means of a colloidal dye, it was shown that with certain inflammatory irritants the normal permeability of capillaries is increased about twofold. Particulate matter which is unable to pass through the normal capillary endothelium readily passes through the lining of such channels in an inflamed area.[3]

These findings are applicable to micro-organisms. When bacteria, as *B. prodigiosus* or *B. pyocyaneus*, are injected into the circulating blood stream they localise and are recovered from foci of inflammation in greater numbers than from surrounding normal tissues. This was found by culturing inflamed skin areas and by comparing the number of colonies obtained with those recovered from corresponding normal cutaneous regions. Bacteria when injected directly into an area of injury are likewise fixed in situ precisely as in the case of the vital dye described previously, and these micro-organisms fail to disseminate to the tributary lymphatics as readily as they do under normal circumstances. The frequent localisation of bacteria from the blood stream in a *locus minoris resistentiæ* after preliminary trauma or other injury to tissue is well known to pathologists and clinicians. Osteomyelitic conditions are the common consequences of such preliminary injury. My observations on the accumulation of bacteria in an inflamed area from the circulating blood stream may explain the mechanism of this phenomenon in terms of increased capillary permeability with subsequent accumulation and fixation of bacteria at the point of injury.[3]

---

A thrombosed lymphatic vessel in a zone of inflammatory infiltration.

"FIXATION"

The mechanism of fixation whereby foreign substances or bacteria fail to disseminate readily from an acutely inflamed focus is referred to an obstructive barrier in the form of thrombosed lymphatics and coagulated plasma in tissues distended with œdema.[4] Time does not permit description of the various experiments to substantiate this concept. The important evidences will be mentioned briefly.

In the first place phagocytosis does not play a significant rôle in the reaction of fixation. This phenomenon occurs so early after the introduction of an irritant that there are still relatively few leucocytes present at the time. Furthermore, microscopic studies at this period fail to reveal any trace of the phagocyted material tested. Yet these foreign substances are prevented from reaching the regional lymph nodes.

Microscopic examination of such acutely inflamed areas reveals a tissue distended with coagulated plasma. The presence of a fibrinous meshwork forms a conspicuous feature of the injured part. Careful observation of small vessels invariably brings to view many of the lymphatics either completely or largely occluded by thrombi consisting of a delicate fibrinous reticulum. In the later stages of the reaction, many leucocytes are found embedded in its meshes (see Figure).

Subsequent experimental evidences substantiated this concept of mechanical obstruction to account for the inability of foreign substances or bacteria to disseminate from an inflamed focus. For instance, it was reasoned that if this were the case, a testing substance, such as a dye or bacteria, would, when injected at the periphery of an inflamed area, fail to enter it. This was found to be the case.

The concept of mechanical obstruction was further established by a chemical test. Concentrated urea in vitro prevents the coagulation of blood, owing to its protein solvent action on fibrin. Preformed fibrin also tends to go into solution fairly readily in the presence of a sufficiently concentrated solution of urea crystals. When this substance is injected into a rabbit simultaneously with an inflammatory irritant, the reaction of fixation is inhibited. In such experiments the lymphatics are found unoccluded by thrombi, thus adequately accounting for the free drainage of substances from the inflamed area.[5]

INVASIVE POWERS OF PYOGENIC ORGANISMS

The foregoing observations have offered a means of studying the mechanism to account for the differences in the invasive ability of various pyogenic organisms. The importance of such a study requires no special emphasis.

The intensity and rapidity with which an inflammatory irritant is circumscribed in a tissue area varies with the type of irritant. The speed with which an irritant causes a region to be walled-off by mechanical obstruction in the form of thrombosed lymphatics or a fibrinous network or both is necessarily an important index in determining its ability to disseminate ultimately into the circulating blood. This holds true if the irritant, per se, can readily drain through lymphatic vessels from the site of inoculation. That bacteria disseminate from the site of inoculation through lymphatics has often been demonstrated. It follows from this that if bacteria are employed as inflammatory irritants some information may be obtained concerning the invasive capacities of different micro-organisms. This would depend on the type of inflammatory reaction which a given micro-organism induces in the host. Pathologists and surgeons are familiar enough with the localising tendency of staphylococcus in contrast to the invasive property of the streptococcus. Can the behaviour of various pyogenic organisms in tissues be related at least in part to their respective abilities of creating an early inflammatory reaction at the site of their inoculation which would tend to prevent, by the mechanism previously described, their dissemination to the tributary lymphatic nodes? It has been pointed out in a previous communication that when a vital dye is introduced into an area at various intervals of time after bacterial inoculation of this site, the degree of walling-off of the infected focus may be determined by the extent to which the dye can drain into the regional lymphatics or, for that matter, ultimately into the blood stream. This method can perhaps be used as a clinical test to determine the patency of lymphatics, or, in other words, the degree of walling-off of an area of inflammation such as a pyogenic abscess or an inflammatory reaction in a cavity, whether the peritoneal, pleural, or joint cavity.

The observations presently to be described represent a comparison of three pyogenic cocci: *Staphylococcus aureus, Streptococcus hæmolyticus*, and Type I. pneumococcus, with regard to the rapidity of retention of trypan-blue at inflammatory foci induced by these respective organisms.[6] The significance of such data in regard to an understanding of the invasive properties of these micro-organisms will be pointed out.

When trypan-blue is injected into the skin of a rabbit immediately after the inoculation of *Staphylococcus aureus*, the dye readily diffuses to the regional lymphatics. If, however, an interval of only one hour elapses between the injection of the bacterial irritant and that of the dye, the latter fails to drain into the lymphatics. An area of inflammation induced by the staphylococcus organism becomes evidently very rapidly circumscribed. Microscopic studies fully substantiate this fact, for lymphatic lumina are found occluded by fibrinous thrombi. In many areas the injured tissues are distended by coagulated plasma.

In the case of Type I. pneumococcus, the dye fails to reach the lymphatic nodes until a somewhat later stage—i.e., about six hours after the inoculation of the micro-organisms. Here again this observation is correlated by the finding of occluding thrombi in lymphatics. It is of interest to note the absence of fibrin in the extra-capillary spaces of the skin of these infected rabbits.

The prompt walling-off response on the part of staphylococcus is contrasted by the delayed reaction of fixation in the case of the hæmolytic streptococcus. When these organisms are inoculated into the cutaneous tissues of rabbits, trypan-blue freely drains from the site of bacterial inoculation to the regional lymphatic vessels for almost two days. Throughout this period the lymphatics are patent, as evidenced both by their normal functioning and by the distended and almost unoccluded state of their lumina. About 45–50 hours after the initial inoculation of the streptococcus, microscopic examination reveals plugging of lymphatics by dense leucocytic thrombi. At this time the area of inflammation is effectively circumscribed, for trypan-blue injected into such an area is fixed and is unable to drain to the regional lymphatic nodes. These observations present an interesting paradox. Staphylococci produce in general little systemic effect owing to their intense local injurious reaction which fixes them in situ. Streptococci produce profound generalised effects on the organism as a whole because of their comparatively mild local reaction which allows them a relatively free penetration to the essential organs.

It is improbable that the interesting observations of Tillett and Garner on the fibrinolytic activity of hæmolytic streptococci can offer an adequate explanation for this delayed fixation of trypan-blue.[7] Their own findings definitely show that this lytic effect fails to take place with the plasma clot of the rabbit which was the animal used in our studies. It is more likely that in the case of human streptococcal infection the dissolution of fibrin acts as a synergistic agent to a more fundamental factor which holds true for both human and rodent types of infection.

Studies now in progress support this point of view. The Berkefeld filtrates of several-day-old broth cultures of *S. aureus* induce an acute inflammatory reaction in the skin of rabbits which promptly causes retention of trypan-blue. The reaction is essentially indistinguishable from that obtained when the micro-organisms alone are injected. Heating the filtrate to 58° C. for about one hour destroys the principle responsible for the reaction. The filtrate of a 24-hour culture is ineffective, whereas the 1-day-old culture of the organisms produces perfect walling-off of the inflamed area. This indicates that the *S. aureus* owes its necrotising activity (which doubtless is an important factor in its ultimate localisation) not merely to its presence per se, but in addition also to its ability to release a powerful exotoxin-like product. This soluble toxic, thermolabile material is capable of inducing sufficient capillary and lymphatic damage to produce a shunting off, so to speak, of the inflamed area. There is some evidence that this material is identical with or at least resembles in many respects staphylococcus leucocidin. The filtrates of hæmolytic streptococci and of Type I. pneumococcus are utterly unable to induce any such response. The dye penetrates from such inflamed areas to the regional lymphatics even as late as 50 hours following the inoculation of streptococcal filtrates. The filtrates of these latter micro-organisms are evidently entirely innocuous.[8]

CONCLUSION

I have called attention to the rôle of the inflammatory reaction in immunity and thereby its relation to some problems in surgery. Powerfully necrotising irritants produce as a result of an increase in capillary permeability and of lymphatic damage an extremely prompt reaction, perhaps best termed fixation. By this process, consisting in the rapid formation of a network of fibrin and of thrombi in lymphatics, the area of injury is mechanically circumscribed and the dissemination of the irritant is prevented. *S. aureus* is an example of such a bacterial irritant. Aleuronat is a chemical irritant of similar potency. Mild irritants, on the other hand, produce only a delayed reaction, thus allowing relatively free penetration of the irritant into the circulation for a considerable interval of time. Occlusion of the draining lymphatics in such instances often takes place as late as two days subsequently to the inoculation of the irritant. Hæmolytic streptococci exemplify this type of irritant. Another instance has been recently demonstrated by McMaster and Hudack who showed that for 24–48 hours following a mere skin incision or a mild burn, lymph drainage is increased. Subsequently the rate of flow is diminished.[9]

In relatively large suppurating or acutely inflamed areas the reaction of fixation may occur as early as 30 minutes after the injection of an irritant. This prompt response allows a definite interval of time for the relatively sluggish leucocytes to assemble for phagocytosis at the site of inflammation. The polymorphonuclear cells appear first and are displaced subsequently by the macrophages. This cytological sequence, as recently demonstrated in this laboratory, is apparently conditioned by changes in the local hydrogen-ion concentration.[10] The reaction of fixation by circumscribing the irritant in the earliest phase of the acute inflammatory reaction plays a definite rôle in immunity, for it protects the organism at the expense of local injury. The reason for the disastrous effects resulting from untimely surgical interference with such an effective inflammatory barrier, as described above, and which is encountered, for example, in the staphylococcus or the anthrax carbuncle, is obvious and needs no further comment in view of the foregoing discussion.

AN ARM-BATH AT RISING TEMPERATURE

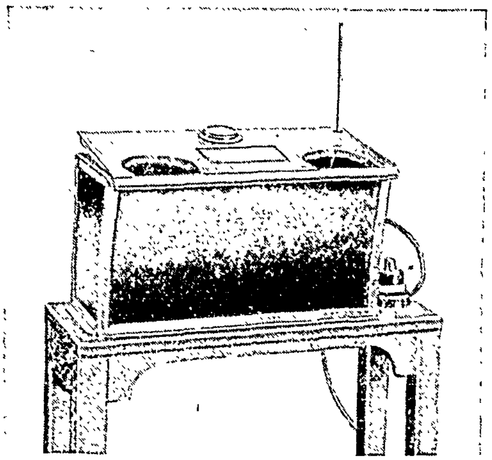
FOR RELIEF OF VASCULAR HYPERTENSION*

By R. Fortescue Fox, M.D., F.R.C.P. Lond.

Partial baths at temperatures plus or minus to the body have been used for many years. *Cold* Sitz baths, douches, and packs with frictions formed a great part of the empirical "hydropathic" system in the last century. The local application of *heat*, sometimes at increasing temperature, is an old practice, especially in Germany, and hot foot-baths have been long employed for hypertensive and nervous affections, bronchial irritation, and asthma at some of the French spas.

Schweninger, whose help in "maintaining his health for two decades" is acknowledged in Bismarck's "Recollections," appears to have been the first, in the early 1870's, to make use of local baths of increasing temperature in a systematic manner in the treatment of general diseases. Disorders of the heart and circulation, congestive abdominal conditions, fever, and other illnesses were treated by him in this way. Since his time the rationale of the general reaction which follows local stimulation has been experimentally demonstrated. A fact of common experience has received its proof although its therapeutic implications are still to a large extent unrealised. It has been shown, for example, by means of the plethysmograph, that if one arm is treated with increasing heat the volume of the *untreated* arm increases, that is to say, the vascular dilatation in one limb is accompanied by a general dilatation over the surface of the body—a "con-sensual reaction," according to the terminology of Brown-Sequard. In other words, it is impossible to confine the effect of heat to the part to which it is applied, and the same is true, to a less extent, of cold and mechanical stimuli.

Following Schweninger, Hauffe[1] has made a series of clinical and experimental studies in Berlin of the effects of partial baths on the circulation, and his conclusions are of much interest and originality. He divides local stimuli into two classes, according to their physiological effects: (1) *sudden or sharp stimuli*, whether by cold in any form, or by heat, or mechanical (by pinching, friction, or movement); (2) *slowly rising stimuli.* Of this class the only definitely active increasing stimulus is that of heat; slowly increasing movements are uncertain in their effects. The plethysmographic curve falls after all forms of sudden stimulus, but rises steadily with the stimulus of slowly increasing heat. It has been clearly shown that this form of local-heat-stimulus brings about a definite general reaction: progressive vasodilatation, increased circulation in the capillaries and veins, and changes in the distribution of the blood. The vasodilatation is believed to affect not only the skin and subcutaneous tissues, muscles, and bones, but also the liver, spleen, bronchial tubes, and coronary vessels. That is to say, the "internal peripheral" circulation is modified and increased by heat applied externally to a single limb. To make this possible the blood is drawn to the outward parts from a central area or reservoir, which includes the cardiac cavities, the pulmonary circulation, and the large arterial trunks and branches up to their entry into the organs. An overstrained heart may thus be relieved by gradual displacement of the blood mass from the reservoir to the outward districts, without effort on the part of the heart but solely by direction of its energy to the altered peripheral surfaces. The pressure of the blood proportionately decreases as the surface of the body increases, and an increase in the surface circulation diminishes the cardiac burden. With this may be compared the effect of sudden hot or cold stimuli, which should always be avoided when the heart is embarrassed.



The arm-bath

The rising foot-bath is recommended only for robust subjects, the arm-bath being also preferable from the extent and proximity of the surface operated on. The relation of skin areas to organs and functions should not be overlooked. In partial baths of rising temperature the technique, duration, temperature, as well as exact observation of the extension of the reactions on the surface of the body, are of great importance.

The late Dr. Anton Lieven[2] recently summarised a long experience in this method of treatment at Aachen.

> In his practice the three following types of cases showed good results: (1) residual articular rheumatism after rheumatic fever, with or without valvular lesions or myocarditis; (2) rheumatoid or osteo-arthritis with hyperpiesis; (3) Bauer's syndrome or "high-pressure rheumatism," that is, pseudo-rheumatic symptoms in the soft tissues, disappearing when the blood pressure is reduced. If arterio-sclerosis was not far advanced, marked lowering of tension was often observed—e.g., from 220 to 170. Young patients were commonly given from three to four weeks of nearly daily baths. In older people the temperatures and intervals varied with the reaction. But in all cases he found that, properly given, the arm-bath relieved rather than put any strain upon the heart. Hans Behrend has also put on record a similar experience at the hydrotherapeutic clinic of the University of Berlin.[3]

The bath here figured, the first of its kind in England, differs in some respects from the German model. It has been made, to my design, by Charles Hearson and Co., Bermondsey, for Dr. Mary Nicol, of Southend. Both the arms are here immersed in a single bath at about blood heat. The water is gradually warmed by an electrical resistance, giving a uniform augmentation of heat in unit time of 1° F. per minute, measured by rototherm and mercurial thermometers. Thus a bath of 12 to 20 minutes' duration would begin at 100° and finish at 112° or 120°. I am not competent to express an opinion on the physiological hypotheses that have been put forward to explain its action. But I can state that my own preliminary observations in cases of vascular hypertension show a fall in both systolic and diastolic pressure after a single bath, amounting sometimes to 5–15 mm. in the diastolic reading. The systolic reading appears to me of less importance. The reduction of pressure is believed to last for 2–6 hours. The local heat causes little or no discomfort, but some flushing and general perspiration. Pain and breathlessness, if present, are relieved. It seems to be a safe and effectual method of producing, at all events temporarily, a general peripheral dilatation. I should anticipate that, with suitable technique, augmenting heat will be found of especial value in the common variety of high blood pressure, which shows periodical "crises" or "waves"[4, 5] of vascular hypertension; and probably also in many chronic conditions (rheumatic and otherwise) with "poor circulation," angiospasm, subnormal temperature, Raynaud's disease, or chilblains.

---

* Demonstrated at a reception given by the International Society of Medical Hydrology and the British Health Resorts Association at the Institute of Hygiene on March 15th.

In any case, I hope that the claims advanced will be put to the test by medical men having the opportunity of more extended observation, both at the spas and at clinics for physical treatment. Whether the vasodilatation produced by a course of treatment is maintained remains to be proved, but the risks of paroxysmal hypertension are so considerable that even temporary or partial relief should be welcomed.

SKIN SENSITIVITY TO BICHROMATE

By C. E. Hercus, D.S.O., O.B.E., M.D., B.D.S., D.P.H.
PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF OTAGO, NEW ZEALAND; AND
H. D. Purves, M.Sc.

In December, 1932, a boy aged 16 came to the out-patient department of the Dunedin Hospital suffering from dermatitis of the flexor surfaces of both forearms. Since March, 1932, he had been employed by a fur-coat manufacturing firm, where his work was to damp dyed rabbit skins with water applied with a brush. He was well till November, when an irritable papular rash appeared on the flexor surfaces of both wrists; it did not yield to the treatment he used, and it spread up the forearms, so he sought advice at the hospital.

The dermatitis was of a papulo-squamous type with vesication and exudation of serum in places, and extended from wrist to elbow on the flexor aspects of both arms; the skin was reddened and deeply infiltrated. Sedative lotions were prescribed and he continued at work, but as the condition of the skin became worse he was admitted to hospital on Jan. 24th, 1933.

At this date the dermatitis was widespread, affecting the exposed surfaces of his neck and chest and the legs below the knee, while the inflammation on the arms had become more acute, and extensive areas of ulceration were present. In addition, there was severe blepharitis and his nose was obstructed and discharged serum. The acuteness of the dermatitis was quickly subdued by ordinary treatment, and on Feb. 18th he was discharged from hospital. Three months elapsed, however, before the rash and the nose and eye symptoms had completely disappeared. In June he resumed work, but within a fortnight a complete relapse occurred and he was obliged to abandon his employment.

SEARCH FOR THE CAUSE

It was now clear that the dermatitis was of the occupational variety and a search for the causal agent was begun. Samples of furs were obtained from the factory and patch tests were made by applying patches 1 in. square to the patient's skin for 24 hours. Severe reactions were induced by rabbit fur, dyed to imitate seal, and these were more intense when the under-surface of the pelt was applied to the skin. In control tests this pelt induced no reaction on normal persons.

We now obtained from the dyers samples of this fur in different stages of manufacture and patch tests were made. The results were as follows:—

Untreated rabbit skin	negative.
Rabbit skin after tanning and dressing ..	
,, ,, ,, "tipping"	
,, ,, ,, "dipping" (finished fur) ..	+ + +

In the "dipping" process the pelts, after mordanting in a bath of bichromate, are dyed by immersion in a solution of hydrogen peroxide and Ursol D. As ursol D—paraphenylene diamine—has been found to be the causal factor in many cases of fur dermatitis we assumed that it was operative in this case; but no reaction followed the application of ursol D to our patient's skin.

We next obtained from the dyers samples of all the dyes they had in stock, which comprised ursol D, base 1, ursol DB, ursol P, ursol DF, ursol 2G, and ursol SK. (Both ursol D and base 1 are trade synonyms for paraphenylene diamine.) Each of these dyes was applied in 1 per cent. solution on cotton-wool, but no positive reaction was obtained.

Thinking that the reaction must be due to either some combination of the rabbit skin with the dye, or to partially oxidised compounds formed during dyeing, we dyed portions of rabbit pelt with all the above-mentioned dyes. None gave a positive reaction. Next, a sample of fur "tipped" with aniline black was finished by mordanting with bichromate, and then dyeing with ursol D. This piece, identical with the factory product, induced no reaction. Two pieces of rabbit skin, which had been mordanted and washed only, gave a positive reaction. Rabbit pelt mordanted and well washed gave an indeterminate reaction. Cotton-wool and mordanting solution induced an intense reaction. These results may be tabulated thus:—

"Seal tipped" mordanted with bichromate and dyed with ursol D	neg.
"Seal tipped" mordanted with bichromate and rinsed	+
Plain rabbit mordanted with bichromate and rinsed	+
Fresh sample of "rabbit dyed seal" from dyers	+ + +

A further test gave the following results:—

Rabbit pelt mordanted and well washed ..	±
Cotton-wool and mordanting solution ..	+ + + +

These tests show clearly that the reaction induced by the finished factory product was due to traces of bichromate in the pelt. An extract of the pelt made by soaking for six hours in cold water gave the following results:—

0·1 c.cm. extract of pelt	+ +
0·1 c.cm. extract of pelt reduced by the addition of bisulphite	neg.
0·1 c.cm. of 1 in 10,000 solution pot. bichromate ..	+ +

It was estimated that 0·21 mg. of potassium bichromate was extracted from each square inch of pelt. On inquiry

we learnt from the dyers that the furs are given a final treatment by brushing with a solution of bichromate. This dries on the fur, and in the subsequent handling some of the dry powder is rubbed off and becomes fixed to the porous under-surface of the pelt.

LIMITS OF PATIENT'S SENSITIVITY

The limiting amount of bichromate giving a reaction on external application was determined by applying 0·1 c.cm. amounts of the different solutions on lint for 24 hours. The results are set out in Table I.

TABLE I

Concentration of solution of $K_2Cr_2O_7$.	Amount of $K_2Cr_2O_7$ in 0·1 c.cm. millionths of a gramme = 1.	Amount of chromium in 0·1 c.cm.	Reaction after 24 hours.
1 in 10,000	10	3·5	+ + +
1 in 30,000	3·3	1·2	+
1 in 100,000	1	0·35	±
1 in 1,000,000	0·1	0·035	—

The sensitivity to intradermal inoculation was also determined by injections of 0·1 c.cm. (Table II.).

TABLE II

Concentration of $K_2Cr_2O_7$.	$K_2Cr_2O_7$ in 0·1 c.cm.	Chromium in 0·1 c.cm.	Reaction.
1 in 100,000	1	0·35	+ + +
1 in 1 million	0·1	0·035	+ +
1 in 3 millions	0·033	0·012	+ +
1 in 10 ,,	0·01	0·0035	+
1 in 30 ,,	0·0033	0·0012	+
1 in 100 ,,	0·001	0·00035	±
1 in 500 ,,	..	..	—
1 in 1000 ,,	..	..	—
Saline	..	..	—

The smallest amount of bichromate giving a definite positive reaction was one three-hundred-millionth of a gramme = 3×10^{-9} g. containing $1{\cdot}2 \times 10^{-9}$ g. of chromium.

Where positive reactions were obtained a redness was observed within four hours of the injection, increasing to a maximum in about eight hours, and at this time some irritation was felt. In about 24 hours fine vesiculation ensued producing a roughness of the skin which persisted for as long as a fortnight after the injections.

SPECIFICITY OF REACTION

Positive reactions have only been obtained with solutions containing chromic acid or its salts. Chromic sulphate and other compounds of trivalent chromium were quite inert, as were solutions of chromates after treatment with reducing agents, such as sulphur dioxide, which reduce chromic acid. The patient was not found to be more sensitive than normal to other irritant substances, the reaction due to formalin solution diluted 1 in 4 being no greater than that in a normal person.

A year later the patient's sensitivity was again determined by intradermal inoculation with the results seen in Table III.

TABLE III

Concentration $K_2Cr_2O_7$.	Reaction.	Concentration $K_2Cr_2O_7$.	Reaction.
1 in 100,000	+ +	1 in 30 millions	±
1 in 1 million	+	1 in 100 ,,	—
1 in 3 millions	+	1 in 300 ,,	—
1 in 10 ,,	+		

There appeared to be a slight reduction of sensitivity, the lowest concentration giving a marked reaction being now 1 in 10 million as compared with 1 in 30 million a year before.

The conjunctival reaction was tested but no reaction was obtained with one drop of any of the solutions tested, ranging from 1 in 300 million to 1 in 30,000.

Two attempts at passive transfers were made. In the first, the patient's serum, not inactivated, was injected in amounts of 0·2 c.cm. into one of us (H. D. P.). The injections were followed within five minutes by a marked reaction consisting of irritation with the formation of a central white raised area 1·5 cm. in diameter surrounded by a marked redness. The reaction reached a maximum in half an hour and had practically subsided in three hours' time. The injection of 0·1 c.cm. of 1 in 10,000 bichromate into the serum area was painful owing to the previous irritation, but was not followed by any reaction. A 1 per cent. solution bichromate was also applied externally on cotton-wool to a second serum inoculation, and again no evidence of transfer was obtained.

In a second trial, a year later, the patient's serum was first inactivated half an hour at 60° C. and inoculated into both the authors with normal serum controls. This time no reaction was obtained from the patient's serum. One of us (H. D. P.) was inoculated with a 0·5 per cent. solution of bichromate in saline as antigen. The injections of this concentration were very painful, the pain ceasing as soon as the injection was finished. All the bichromate injections showed redness and tenderness for one week after the injection, and by this time the skin over the sites became rough and scaly, but there was never any vesiculation. A month after the injections the scaliness had practically disappeared and only a slight dusky pigmentation remained, probably due to precipitation of chromium compounds beneath the skin. There was no evidence of transfer, both serum areas and the bichromate control reacting similarly.

In the other test (C. E. H.) a 1 in 10,000 solution of bichromate was used as antigen as 1 in 1000 bichromate was found to be painful on injection. There was no reaction and no evidence of transfer.

DISCUSSION

It has long been known that workers exposed to chromic acid and its salts develop ulcers and rashes, some people being more susceptible than others. Joules [1] reports a case of asthma from sensitisation to bichromate. The skin of this patient was sensitive to a solution of one grain of potassium bichromate in 25 minims, and injection of gr. 1/25 $K_2Cr_2O_7$ brought on asthmatic symptoms. Smith [2] has reviewed the literature respecting allergic reactions to chromates, and reports a case, with asthma and allergic manifestation, sensitive to 1 per cent. ammonium bichromate in the patch test. After 24 hours there was erythema followed by vesiculation in three days. Intradermal injection of 0·1 c.cm. of 0·5 per cent. ammon. bichromate produced a marked local reaction and a lighting up of distant areas. Humphrey and Phillips [3] found small quantities of chromate extractable from some leathers. Dr. Cox, discussing the paper, said the quantities were small, not exceeding 1 mg., and did not think this would cause dermatitis to anybody.

In the case we record the sensitivity shown to chromate is remarkable. Intradermal inoculation appears to be the most delicate test for chromic acid. It surpasses any of the chemical tests.

J. W. Mellor, in his "Comprehensive Treatise on Inorganic and Theoretical Chemistry," cites Jackson for the statement that the precipitation reaction between barium salt and potassium dichromate has a limit of 1 in 256,000 dichromate. In the same volume Mellor states that König finds the colour reaction with 1 : 8 dihydroxynaphthalene 3 : 6 disulphonate is sensitive to 0·000,000,8 g. chromate in 10 c.cm. Our patient has given a definite reaction with 0·1 c.cm. of 1 in 30 million bichromate equivalent to 0·000,000,0012 g. chromate in 0·1 c.cm.

This study shows the importance of searching investigation by the use of specific tests, and raises the question of whether other cases of fur dermatitis, reported as due to parathenylene diamine, may not have been caused by traces of bichromate in the finished fur. In persons with sensitivity of this high order, dermatitis due to the presence of chromates in leather articles used by them is likely to occur.

The mechanism of sensitisation to a simple inorganic substance like chromic acid remains obscure. As in previous experiments, our attempt to secure passive transfer failed. The reaction shown with the patient's serum in our first trial is of particular interest, since a similar reaction was demonstrated by previous experimenters. We cannot, at present, say whether failure to obtain this reaction in our second experiment was due to previous inactivation of the serum.

SUMMARY

A case showing a high degree of specific sensitisation to chromates is reported. A definite skin reaction was obtained with 0·000,0033 g. of potassium bichromate applied externally, and with 0·000,000,0033 g. on intradermal inoculation. Attempts at passive transfer yielded negative results.

Clinical and Laboratory Notes

EMPYEMA NECESSITATIS SIMULATING PERINEPHRIC ABSCESS AND CURED BY ASPIRATION

By E. H. W. DEANE, M.B. Melb.
ASSISTANT MEDICAL SUPERINTENDENT, WRIGHTINGTON HOSPITAL
(LANCASHIRE COUNTY COUNCIL)

ADVANCES in the diagnosis and treatment of intrapleural suppuration have made empyema necessitatis rare. The pus, however, may appear in many and interesting situations, and at times the diagnosis of its origin has caused no little difficulty; thus Birch[1] reported a case in which infection had actually entered the spinal canal causing paraplegia. The following record is of interest because the pus tracked to the region of the upper pole of the kidney, presumably by passing under the external arcuate ligament, and the signs resembled those of perinephric abscess. In fact, the patient presenting himself with a swelling in the loin, the condition was regarded as one of primary perinephric suppuration with upward extension through the diaphragm and subsequent involvement of the pleura.

Y. Z., a mill operative aged 22, had had left-sided pneumonia three years previously. The illness lasted a fortnight and left him with a chronic cough, and he did not regain his strength. The cough and weakness persisted for two and a half years, but apparently the chest was not re-examined. Four months before admission to the Wrightington Hospital a swelling appeared in the left loin; it was recognised as an abscess and incised twice, and the diagnosis of perinephric abscess made. The chest condition being discovered at the same time was regarded as secondary to the perinephric infection. There had been no disturbance of renal function. The patient was then admitted to hospital and was found to be a pale-looking youth with two sinuses (incisions) discharging profusely in the left loin below the 12th rib. He ran an irregular evening temperature of 101–102° F. He had conspicuous clubbing of the fingers; the left side of the chest was flattened, with poor air-entry; and there were all the physical signs of a large effusion in the lower half. There was no deformity or tenderness of the spine suggesting a vertebral origin of the infection, and this was confirmed radiologically; nor was any urinary abnormality detected, or radiographic abnormality of the renal tracts.

X ray examination of the chest showed a large fluid opacity with horizontal upper level extending as high as the 2nd rib in front. This pleural effusion was evacuated through an aspirating needle passed through an intercostal space, and the pleural cavity was washed out with eusol solution. At the completion of this operation 20 c.cm. of a 2 per cent. solution of mercurochrome was introduced through the needle into the pleural cavity, and next day the discharge from the sinuses was coloured with this dye —proving the connexion with the empyema. The aspirated pus was found to contain many disintegrating polymorph leucocytes, staphylococci, and streptococci, but no tubercle bacilli were seen either in films or after guinea-pig inoculation. Eusol washing-out was repeated at two-day intervals and the discharge from the sinuses became much less. After about a week it was found possible to pass a rubber catheter through one of the sinuses into the empyema cavity and to carry on with the eusol washing by this route. This treatment was then continued daily until a month after the patient's admission, when the fluid from the empyema became clear and serous; active treatment was then discontinued and the sinuses rapidly closed, and have remained closed since.

During treatment the patient lost all trace of cough, and radiography before discharge from hospital showed that the lung had almost completely expanded and filled the chest except for a small opaque area in the costophrenic angle. The weight in two months increased by 17 lb. and the blood sedimentation index improved from 32 to 12 mm. (Cutler's method).

It seems almost certain that in this case the empyema had been present since the attack of pneumonia three years previously; that it was of long standing seemed probable from the flattened state of the left side of the chest. An empyema persisting for so long usually leads to considerable thickening of the pleura, and this may prevent re-expansion of the lung, so that surgery is required either to permit re-expansion or to collapse the chest wall in order to obliterate the pleural cavity. The fact that simple aspiration followed by eusol irrigation has allowed of re-expansion in a case of such long standing is an additional reason for the present report. A similar successful result after aspiration has been recorded by Khan.[2]

I am indebted to Dr. E. H. Allon Pask, medical superintendent of Wrightington Hospital, for permission to publish these notes.

LOBAR ATELECTASIS IN AN ADULT

WITH RE-EXPANSION

By ERNEST FLETCHER, M.B.Camb., M.R.C.P.
ASSISTANT PHYSICIAN TO QUEEN MARY'S HOSPITAL FOR THE EAST END, AND THE ITALIAN HOSPITAL; AND
S. B. DIMSON, M.B.Lond., D.T.M.
LATE HOUSE PHYSICIAN AT QUEEN MARY'S HOSPITAL

THE increasing use and improved technique of radiology is steadily adding to our knowledge of lung disease. Foremost among the advances of radiological work has been the employment of lipiodol in diagnosis. Thus the existence in certain chest radiographs of a triangular shadow at the base of either lung has been known for many years, but the interpretation put on it was by no means clear.

Originally it was thought to be that of a mediastinal effusion or even pleural thickening.[1] It was subse-

we learnt from the dyers that the furs are given a final treatment by brushing with a solution of bichromate. This dries on the fur, and in the subsequent handling some of the dry powder is rubbed off and becomes fixed to the porous under-surface of the pelt.

LIMITS OF PATIENT'S SENSITIVITY

The limiting amount of bichromate giving a reaction on external application was determined by applying 0·1 c.cm. amounts of the different solutions on lint for 24 hours. The results are set out in Table I.

TABLE I

Concentration of solution of $K_2Cr_2O_7$.	Amount of $K_2Cr_2O_7$ in 0·1 c.cm. millionths of a gramme = 1.	Amount of chromium in 0·1 c.cm.	Reaction after 24 hours.
1 in 10,000 ..	10	3·5	+ + +
1 in 30,000 ..	3·3	1·2	+
1 in 100,000	1	0·35	±
1 in 1,000,000	0·1	0·035	—

The sensitivity to intradermal inoculation was also determined by injections of 0·1 c.cm. (Table II.).

TABLE II

Concentration of $K_2Cr_2O_7$.	$K_2Cr_2O_7$ in 0·1 c.cm.	Chromium in 0·1 c.cm.	Reaction.
1 in 100,000 ..	1	0·35	+ + +
1 in 1 million ..	0·1	0·035	+ +
1 in 3 millions ..	0·033	0·012	+ +
1 in 10 ,, ..	0·01	0·0035	+
1 in 30 ,, ..	0·0033	0·0012	+
1 in 100 ,, ..	0·001	0·00035	±
1 in 500 ,, ..	..	..	—
1 in 1000 ,, ..	..	..	—
Saline	..	..	—

The smallest amount of bichromate giving a definite positive reaction was one three-hundred-millionth of a gramme = 3×10^{-9} g. containing $1{\cdot}2 \times 10^{-9}$ g. of chromium.

Where positive reactions were obtained a redness was observed within four hours of the injection, increasing to a maximum in about eight hours, and at this time some irritation was felt. In about 24 hours fine vesiculation ensued producing a roughness of the skin which persisted for as long as a fortnight after the injections.

SPECIFICITY OF REACTION

Positive reactions have only been obtained with solutions containing chromic acid or its salts. Chromic sulphate and other compounds of trivalent chromium were quite inert, as were solutions of chromates after treatment with reducing agents, such as sulphur dioxide, which reduce chromic acid. The patient was not found to be more sensitive than normal to other irritant substances, the reaction due to formalin solution diluted 1 in 4 being no greater than that in a normal person.

A year later the patient's sensitivity was again determined by intradermal inoculation with the results seen in Table III.

TABLE III

Concentration $K_2Cr_2O_7$.	Reaction.	Concentration $K_2Cr_2O_7$.	Reaction.
1 in 100,000 ..	+ +	1 in 30 millions ..	±
1 in 1 million ..	+	1 in 100 ,, ..	—
1 in 3 millions ..	+	1 in 300 ,, ..	—
1 in 10 ,, ..	+		

There appeared to be a slight reduction of sensitivity, the lowest concentration giving a marked reaction being now 1 in 10 million as compared with 1 in 30 million a year before.

The conjunctival reaction was tested but no reaction was obtained with one drop of any of the solutions tested, ranging from 1 in 300 million to 1 in 30,000.

Two attempts at passive transfers were made. In the first, the patient's serum, not inactivated, was injected in amounts of 0·2 c.cm. into one of us (H. D. P.). The injections were followed within five minutes by a marked reaction consisting of irritation with the formation of a central white raised area 1·5 cm. in diameter surrounded by a marked redness. The reaction reached a maximum in half an hour and had practically subsided in three hours' time. The injection of 0·1 c.cm. of 1 in 10,000 bichromate into the serum area was painful owing to the previous irritation, but was not followed by any reaction. A 1 per cent. solution bichromate was also applied externally on cotton-wool to a second serum inoculation, and again no evidence of transfer was obtained.

In a second trial, a year later, the patient's serum was first inactivated half an hour at 60° C. and inoculated into both the authors with normal serum controls. This time no reaction was obtained from the patient's serum. One of us (H. D. P.) was inoculated with a 0·5 per cent. solution of bichromate in saline as antigen. The injections of this concentration were very painful, the pain ceasing as soon as the injection was finished. All the bichromate injections showed redness and tenderness for one week after the injection, and by this time the skin over the sites became rough and scaly, but there was never any vesiculation. A month after the injections the scaliness had practically disappeared and only a slight dusky pigmentation remained, probably due to precipitation of chromium compounds beneath the skin. There was no evidence of transfer, both serum areas and the bichromate control reacting similarly.

In the other test (C. E. H.) a 1 in 10,000 solution of bichromate was used as antigen as 1 in 1000 bichromate was found to be painful on injection. There was no reaction and no evidence of transfer.

DISCUSSION

It has long been known that workers exposed to chromic acid and its salts develop ulcers and rashes, some people being more susceptible than others. Joules[1] reports a case of asthma from sensitisation to bichromate. The skin of this patient was sensitive to a solution of one grain of potassium bichromate in 25 minims, and injection of gr. 1/25 $K_2Cr_2O_7$ brought on asthmatic symptoms. Smith[2] has reviewed the literature respecting allergic reactions to chromates, and reports a case, with asthma and allergic manifestation, sensitive to 1 per cent. ammonium bichromate in the patch test. After 24 hours there was erythema followed by vesiculation in three days. Intradermal injection of 0·1 c.cm. of 0·5 per cent. ammon. bichromate produced a marked local reaction and a lighting up of distant areas. Humphrey and Phillips[3] found small quantities of chromate extractable from some leathers. Dr. Cox, discussing the paper, said the quantities were small, not exceeding 1 mg., and did not think this would cause dermatitis to anybody.

In the case we record the sensitivity shown to chromate is remarkable. Intradermal inoculation appears to be the most delicate test for chromic acid. It surpasses any of the chemical tests.

J. W. Mellor, in his "Comprehensive Treatise on Inorganic and Theoretical Chemistry," cites Jackson for the statement that the precipitation reaction between barium salt and potassium dichromate has a limit of 1 in 256,000 dichromate. In the same volume Mellor states that König finds the colour reaction with 1 : 8 dihydroxynaphthalene 3 : 6 disulphonate is sensitive to 0·000,000,8 g. chromate in 10 c.cm. Our patient has given a definite reaction with 0·1 c.cm. of 1 in 30 million bichromate equivalent to 0·000,000,0012 g. chromate in 0·1 c.cm.

This study shows the importance of searching investigation by the use of specific tests, and raises the question of whether other cases of fur dermatitis, reported as due to parathenylene diamine, may not have been caused by traces of bichromate in the finished fur. In persons with sensitivity of this high order, dermatitis due to the presence of chromates in leather articles used by them is likely to occur.

The mechanism of sensitisation to a simple inorganic substance like chromic acid remains obscure. As in previous experiments, our attempt to secure passive transfer failed. The reaction shown with the patient's serum in our first trial is of particular interest, since a similar reaction was demonstrated by previous experimenters. We cannot, at present, say whether failure to obtain this reaction in our second experiment was due to previous inactivation of the serum.

SUMMARY

A case showing a high degree of specific sensitisation to chromates is reported. A definite skin reaction was obtained with 0·000,0033 g. of potassium bichromate applied externally, and with 0·000,000,0033 g. on intradermal inoculation. Attempts at passive transfer yielded negative results.

Clinical and Laboratory Notes

EMPYEMA NECESSITATIS SIMULATING PERINEPHRIC ABSCESS AND CURED BY ASPIRATION

BY E. H. W. DEANE, M.B. Melb.
ASSISTANT MEDICAL SUPERINTENDENT, WRIGHTINGTON HOSPITAL
(LANCASHIRE COUNTY COUNCIL)

ADVANCES in the diagnosis and treatment of intrapleural suppuration have made empyema necessitatis rare. The pus, however, may appear in many and interesting situations, and at times the diagnosis of its origin has caused no little difficulty; thus Birch [1] reported a case in which infection had actually entered the spinal canal causing paraplegia. The following record is of interest because the pus tracked to the region of the upper pole of the kidney, presumably by passing under the external arcuate ligament, and the signs resembled those of perinephric abscess. In fact, the patient presenting himself with a swelling in the loin, the condition was regarded as one of primary perinephric suppuration with upward extension through the diaphragm and subsequent involvement of the pleura.

Y. Z., a mill operative aged 22, had had left-sided pneumonia three years previously. The illness lasted a fortnight and left him with a chronic cough, and he did not regain his strength. The cough and weakness persisted for two and a half years, but apparently the chest was not re-examined. Four months before admission to the Wrightington Hospital a swelling appeared in the left loin; it was recognised as an abscess and incised twice, and the diagnosis of perinephric abscess made. The chest condition being discovered at the same time was regarded as secondary to the perinephric infection. There had been no disturbance of renal function. The patient was then admitted to hospital and was found to be a pale-looking youth with two sinuses (incisions) discharging profusely in the left loin below the 12th rib. He ran an irregular evening temperature of 101–102° F. He had conspicuous clubbing of the fingers; the left side of the chest was flattened, with poor air-entry; and there were all the physical signs of a large effusion in the lower half. There was no deformity or tenderness of the spine suggesting a vertebral origin of the infection, and this was confirmed radiologically; nor was any urinary abnormality detected, or radiographic abnormality of the renal tracts.

X ray examination of the chest showed a large fluid opacity with horizontal upper level extending as high as the 2nd rib in front. This pleural effusion was evacuated through an aspirating needle passed through an intercostal space, and the pleural cavity was washed out with eusol solution. At the completion of this operation 20 c.cm. of a 2 per cent. solution of mercurochrome was introduced through the needle into the pleural cavity, and next day the discharge from the sinuses was coloured with this dye —proving the connexion with the empyema. The aspirated pus was found to contain many disintegrating polymorph leucocytes, staphylococci, and streptococci, but no tubercle bacilli were seen either in films or after guinea-pig inoculation. Eusol washing-out was repeated at two-day intervals and the discharge from the sinuses became much less. After about a week it was found possible to pass a rubber catheter through one of the sinuses into the empyema cavity and to carry on with the eusol washing by this route. This treatment was then continued daily until a month after the patient's admission, when the fluid from the empyema became clear and serous; active treatment was then discontinued and the sinuses rapidly closed, and have remained closed since.

During treatment the patient lost all trace of cough, and radiography before discharge from hospital showed that the lung had almost completely expanded and filled the chest except for a small opaque area in the costophrenic angle. The weight in two months increased by 17 lb. and the blood sedimentation index improved from 32 to 12 mm. (Cutler's method).

It seems almost certain that in this case the empyema had been present since the attack of pneumonia three years previously; that it was of long standing seemed probable from the flattened state of the left side of the chest. An empyema persisting for so long usually leads to considerable thickening of the pleura, and this may prevent re-expansion of the lung, so that surgery is required either to permit re-expansion or to collapse the chest wall in order to obliterate the pleural cavity. The fact that simple aspiration followed by eusol irrigation has allowed of re-expansion in a case of such long standing is an additional reason for the present report. A similar successful result after aspiration has been recorded by Khan.[2]

I am indebted to Dr. E. H. Allon Pask, medical superintendent of Wrightington Hospital, for permission to publish these notes.

LOBAR ATELECTASIS IN AN ADULT

WITH RE-EXPANSION

BY ERNEST FLETCHER, M.B.CAMB., M.R.C.P.
ASSISTANT PHYSICIAN TO QUEEN MARY'S HOSPITAL FOR THE EAST END, AND THE ITALIAN HOSPITAL; AND
S. B. DIMSON, M.B.LOND., D.T.M.
LATE HOUSE PHYSICIAN AT QUEEN MARY'S HOSPITAL

THE increasing use and improved technique of radiology is steadily adding to our knowledge of lung disease. Foremost among the advances of radiological work has been the employment of lipiodol in diagnosis. Thus the existence in certain chest radiographs of a triangular shadow at the base of either lung has been known for many years, but the interpretation put on it was by no means clear.

Originally it was thought to be that of a mediastinal effusion or even pleural thickening.[1] It was subse-

we learnt from the dyers that the furs are given a final treatment by brushing with a solution of bichromate. This dries on the fur, and in the subsequent handling some of the dry powder is rubbed off and becomes fixed to the porous under-surface of the pelt.

LIMITS OF PATIENT'S SENSITIVITY

The limiting amount of bichromate giving a reaction on external application was determined by applying 0·1 c.cm. amounts of the different solutions on lint f 24 hours. The results are set out in Table I.

TABLE I

Concentration of solution of $K_2Cr_2O_7$.	Amount of $K_2Cr_2O_7$ in 0·1 c.cm. millionths of a gramme = 1.	Amount of chromium in 0·1 c.cm.	Reaction : 24 ho
1 in 10,000 ..	10	3·5	+ +
1 in 30,000 ..	3·3	1·2	+
1 in 100,000	1	0·35	±
1 in 1,000,000	0·1	0·035	—

The sensitivity to intradermal inoculation w determined by injections of 0·1 c.cm. (Table II.).

TABLE II

Concentration of $K_2Cr_2O_7$.	$K_2Cr_2O_7$ in 0·1 c.cm.	Chromium in 0·1 c.cm.
1 in 100,000 ..	1	0·35
1 in 1 million ..	0·1	0·035
1 in 3 millions ..	0·033	0·012

1 in 100 ,, ..	0·001	0·00035
1 in 500 ,, ..	..	..
1 in 1000 ,, ..	..	..
Saline	..	..

The smallest amount of bichromate givin positive reaction was one three-hundred-mill gramme = 3 × 10—⁹ g. containing 1·2 × 1 chromium.

Where positive reactions were obtained a observed within four hours of the injection, in a maximum in about eight hours, and at this irritation was felt. In about 24 hours fine ensued producing a roughness of the skin whic for as long as a fortnight after the injections.

SPECIFICITY OF REACTION

Positive reactions have only been obtained wit containing chromic acid or its salts. Chromic and other compounds of trivalent chromium w inert, as were solutions of chromates after treat reducing agents, such as sulphur dioxide, which chromic acid. The patient was not found to sensitive than normal to other irritant substan reaction due to formalin solution diluted 1 in 4 b greater than that in a normal person.

A year later the patient's sensitivity was determined by intradermal inoculation with the r seen in Table III.

TABLE III

Concentration $K_2Cr_2O_7$.	Reaction.	Concentration $K_2Cr_2O_7$.	Reaction
1 in 100,000 ..	+ +	1 in 30 millions ..	±
1 in 1 million ..	+	1 in 100 ,, ..	—
1 in 3 millions ..	+	1 in 300 ,, ..	—
1 in 10 ,, ..	+		

There appeared to be a slight reduction of sensitivity, the lowest concentration giving a marked reaction being now 1 in 10 million as compared with 1 in 30 million a year before.

The conjunctival reaction was tested but no reaction was obtained with one drop of any of the solutions tested, ranging from 1 in 300 million to 1 in 30,000.

oxygen had no curative effect on tuberculosis, and partly because its prolonged use tended to produce anæmia. *Paroxysmal dyspnœa* was another type met with, in which the attacks resembled the "cardiac asthma" of elderly non-tuberculous subjects. This was really due to left ventricular failure, and was accompanied by an increased blood flow through the heart. Both morphia, as Clifford Allbutt had shown, and oxygen had been found of benefit in this condition, but the speaker described the mechanical apparatus devised by J. Plesch, which he suggested was better than either, and which was successful in treating pulmonary œdema with "rattling" expiration. Another type of dyspnœa was due to *anæmia.* In this connexion Dr. Poulton drew attention to the metabolic stimulation of cold. In Alpine resorts the rarefied atmosphere, with its reduced oxygen pressure, stimulated blood formation. He could think of no more fruitful scheme for research in this country than to build a room in which the pressure of the oxygen could be diminished and the air could be conditioned, so that the treatment by diminished oxygen pressure and by cold could be simultaneously investigated.

Dr. R. HILTON said that in spontaneous pneumothorax there was arterial anoxæmia and CO_2 retention. The pressure in the pleural cavity he had measured and found as high as 10 cm. of water. He gave evidence to show that not only was there a venous short circuit, but there was also interference with the veins entering the heart, through the displacement of the mediastinum. In artificial pneumothorax the circulation rate, at first slightly raised, was definitely slowed down after a certain pressure was reached. Tuberculosis itself did not necessarily alter the blood gases, but with advanced lesions anoxæmia occurred. This was removed by artificial pneumothorax. Dr. Hilton showed that artificial pneumothorax did not immobilise the lung. He discussed why tuberculous dyspnœa was sometimes relieved by this measure through its action on the body temperature, the toxæmia, and on the anoxæmia when this existed. He reviewed briefly some of the work on nerve reflexes from the lung, and suggested that whereas true dyspnœa was central and chemical, the cause not always being reflected in the peripheral blood, tachypnœa was peripheral and mechanical through changes in lung tissue.

Dr. W. STOBIE remarked that like every other organ in the body, the respiratory centre required for its functioning an adequate supply of normally healthy blood and nervous energy. Contrary to the statement appearing in many text-books, dyspnœa was not common in early tuberculosis, and when present it was usually due to some other unrelated factor, or to some complication such as pleurisy, spontaneous pneumothorax, or an extension of the disease in the other lung. In cases due to pleurisy, the injection of air between the layers of the pleura to relieve the pain and the dyspnœa had the additional advantage of leaving a space for a future induction of A.P. There were, however, two groups of early cases in which spasmodic dyspnœa simulating bronchial asthma was a well-defined feature. In the first group, with few or no physical or radiological signs but with positive sputum, the presence of caseous root glands might be suspected, with a subsequent rupture into a bronchus. Adrenaline or ephedrine would give rapid relief in these cases. In the other group the "asthmatic" condition might be the result of hypersensitiveness to the tuberculo-protein circulating in the blood. Here desensitation might be possible, combined with the judicious use of tuberculin over a prolonged period. In old fibrotic cases, dyspnœa was of course one of the commonest and often the main symptom; and the main essential in treatment was obviously the cutting down of the patient's activities, thus lessening the demands on the lung. In the terminal stages of the disease, oxygen and CO_2, also Felsol powders, might give relief. Toxic dyspnœa was an indication for collapse therapy. Dyspnœa from the presence of effusion in artificial pneumothorax treatment would usually call for removal of the fluid, and in cases with unduly mobile mediastinum replacement with gomenol instead of air should be considered. When the dyspnœa was due to circulatory rather than to pulmonary causes, collapse therapy was contra-indicated.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY

A MEETING of this society was held in Manchester on April 12th, with Mr. A. GOUGH, the president, in the chair.

Involution of the Uterus

Dr. E. A. GERRARD reported his investigations on uterine involution in the rabbit. In the past, he said, the blood-vessels of the involuting uterus had received little attention compared with the musculature and endometrium. Fatty degeneration had been described as one of the stages of involution but this was probably due to the pathological nature of the material investigated. It appeared that Goodall stood alone in his contention that new vessels are formed within the old ones. As for involution of the muscle cells it was attributed by some authorities to granular atrophy and by others to fatty degeneration. Study of involution in human beings was difficult because of the lack of suitable material, and Dr. Gerrard had therefore investigated it in rabbits killed during the involution and superinvolution periods. In these animals it was found that when the uterus contracts after delivery the lumen of the blood-vessels becomes smaller and the walls are thickened. The muscle fibres are reduced in size by a process of granular atrophy, a considerable amount of its protoplasm being absorbed, but no fatty changes are demonstrable. Involution of the musculature is complete by the ninth day. In the arteries, owing to irregular projections into the lumen, and organisation of the peripheral clots, the intima becomes thickened and the internal elastic lamina appears to be displaced outwards. The internal elastic layer assumes a laminated appearance. With lactation, superinvolution occurs and there is an increased deposition of elastic tissue, especially evident round the veins. Superinvolution is characterised by delay of the granular atrophy of the fibres both of the myometrium and the arterial muscular coats.

Dr. K. V. BAILEY asked whether there was any evidence to show where the elastic tissue originated.—Mr. T. N. A. JEFFCOATE (Liverpool) said that it was interesting that so much elastic tissue should be described as present in super- and sub-involution, and asked how Dr. Gerrard had estimated the amount. He doubted whether there was actually any change in the elastic tissue and thought that the quantity remained constant.—Mr. M. DATNOW (Liverpool) referred to the changes which normally take place in the rabbit uterus at the advent of pregnancy and divided them into those which depended on a constitutional stimulant such as œstrin and progestin, and those which were purely local. He thought that involution was a process of degeneration and absorption. There was a sudden collapse of the whole uterus with interference with its blood-supply, leading to degeneration of the tissues of the uterine wall. He also had never seen fatty degeneration during the process of involution. He felt that Goodall's statement should be reviewed in the light of modern knowledge of hormones.

In reply, Dr. GERRARD said he thought the elastic tissues were derived from connective tissue cells. Examination of the slides left no doubt that there were differences in the amount of elastic tissue in super- and sub-involution.

Dr. GERRARD also reported a case of placenta prævia complicated by adherent meningocele.—Dr. R. NEWTON demonstrated a specimen with sarcomatous change in a fibromyoma of the round ligament. —Dr. C. P. BRENTNALL showed a radiogram of an obliquely contracted pelvis, and Dr. BAILEY showed a granulosa-cell tumour of the right ovary removed from a patient aged 62, a uterus with rudimentary horn and fibroids, and an adenocarcinoma of the cervix removed by extended pan-hysterectomy.

REVIEWS AND NOTICES OF BOOKS

The Treatment of Fractures

By LORENZ BÖHLER, Director of the Hospital for Accidents, Vienna; Lecturer on Surgery in the University of Vienna. Fourth English edition, translated from the fourth enlarged and revised German edition by ERNEST W. HEY GROVES, M.S., M.D., F.R.C.S., Consulting Surgeon, Bristol General Hospital; Emeritus Professor of Surgery, University of Bristol. Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall Ltd. 1935. Pp. 578. 42*s*.

Technique du traitement des fractures

By LORENZ BÖHLER. Translation into French of the fourth edition by M. BOPPE, Chirurgien des Hôpitaux de Paris. Paris: Masson et Cie. 1934. Pp. 653. Fr.160.

THE appearance of French and English editions of Prof. Böhler's important work has made it available to surgeons and to students of surgery throughout the world; but the significance of these translations is greater even than that, for it is a tribute to the widespread admiration felt for Böhler's work in Vienna. Dr. Boppe, the translator into French, has himself been engaged in carrying into practice in the surgical clinics of the Hôtel-Dieu the main principles taught by Böhler, and in a preface Prof. Hartmann, his chief in these clinics, speaks with satisfaction of the results obtained. Mr. Hey Groves has visited the Vienna clinic and been impressed with its methods and with the fundamental principles underlying them. Böhler's great enthusiasm for his subject, the originality of many of his ideas, and the immense amount of care he habitually bestows on the patients under his care are reflected in this work, which is a lasting monument to his hospital. The chief principles of treatment advocated by Böhler are reduction under local anæsthesia of all fractures (including fractures of the spine); immobilisation in an unpadded plaster cast; relegation of open operation to a very subsidiary position; the use of skeletal traction during reduction and application of plaster splints; standardisation of apparatus and methods so as to allow of efficient organisation; and, finally, substitution of early function of limbs and body generally for the methods of physicotherapy, particularly of massage, commonly in use.

While the book under review is perhaps primarily an account of organisation and treatment of these injuries under ideal conditions so as to ensure the most perfect possible functional results and the avoidance of all unnecessary economic waste, it is at the same time an excellent text-book on fractures. Nowhere can be found a clearer description of the mechanics involved in the displacement and reduction of individual fractures. Teaching by diagrammatic drawings has been carried to a fine art; a very great deal can be learned by study of these alone. No detail seems too small to have escaped the author's attention. He explains the reason for completely encircling the chest in fractures of the ribs, as immobilisation of one side alone is not possible when both move in unison at each respiration. The position of most ease in synovitis of the long head of the biceps brachii is illustrated by a careful series of diagrams. The apparent alteration in length of the thigh in different positions of the hip- and knee-joints is also illustrated. This is an important fact to impress on the student, but it is surely a little surprising to find the movable patella taken as the lower fixed point in testing for shortening of the femur, rather than the internal malleolus. One might also query the period of seven to eight weeks as giving sufficient union to allow of weight-bearing in a case of fracture of the shaft of the femur. Few surgeons would agree with this, especially as Böhler apparently does not use a walking calliper splint in the after-treatment. Many surgeons will be inclined to agree with Prof. Hartmann's opinion, expressed in the preface to Dr. Boppe's translation, that Böhler's prejudice against open operation is carried a little too far. Criticism of individual methods of treatment tend, however, to disappear before the intrinsic evidence of personal experience in every section of the book. Böhler wrote in the preface to the third edition that some things which he formerly advised were now relegated to the category of "mistakes." Attention is specifically drawn to these "mistakes" in the text, and this is a good illustration of the spirit in which the author approaches his subject.

The section on fractures of the spine will be a revelation to anyone unfamiliar with the results obtained by modern methods of reduction and early function. Böhler's patients are seen walking about and performing acrobatic exercises in their plaster jackets a few days after the injury. The English translation contains new material in the section dealing with fractures and fracture-dislocations of the cervical spine, and incorporates in the chapter on fractures of the femoral neck the most recent developments of the Sven Johansson technique. Some of the most interesting pages are undoubtedly those contained in Appendix D, which deals with the economic aspect of accidents and the organisation of successful hospital treatment. Both English and French editions are very fully illustrated, and the respective publishers deserve congratulation on the general appearance of the volumes. The translations are excellent.

Dental Caries

Studies in the Ætiology of Dental Caries. By G. GRAHAM MACPHEE, M.D., Ch.B., L.D.S., Hon. Consulting Dental Surgeon, Liverpool Stanley Hospital; Hon. Assistant Surgeon, Liverpool Dental Hospital. London: John Bale, Sons and Danielsson. 1935. Pp. 203. 7*s.* 6*d.*

THIS book falls into two parts: one a summary of existing views on the ætiology of dental caries, and the other an account of some bacteriological investigations carried out by the author on the possibility of an immunological reaction in the disease. It is useful from time to time to have the literature of a disease summarised and the various theories examined critically. But this laborious task must be properly done to be of value. The summary provided in this book is too incomplete to be of much use either as a convenient source of reference or as a reasoned and critical evaluation of the data.

Dr. Macphee's description of experiments on the immunological reactions in dental caries approaches the subject from a new point of view, and demands consideration. He claims to have found a definite precipitin reaction between filtered or centrifugalised emulsions of carious dentine and serum from the same or other subjects. He finds that the intensity of this reaction is greatest in subjects immune to caries as judged by clinical examination, and least in those who show a high susceptibility to caries. Dr. Macphee suggests that this precipitate may account for the calcium barrier in the translucent zone, and that a complete reaction may result in the condition known as arrested caries. Complement-fixation tests give a positive result which is greater with antigen from carious dentine than with antigen from normal dentine. Dr. Macphee draws the conclusion that these reactions suggest that dental caries is a true infective process either due to bacteria or to a filter-passing virus. These views are opposed to much of the current teaching which regards the bacterial factor as being responsible for the formation of acid from carbohydrate fermentation, but not as being itself the causative factor. Immunity and susceptibility are usually regarded as being dependent on structural factors and the physical quality of the diet, though there is much conflict of opinion as to the respective importance of these two factors. Dr. Macphee gives a fresh orientation to a problem which continues to be one of the most baffling in dentistry, and his views will doubtless be investigated.

Treatment by Diet

By CLIFFORD J. BARBORKA, B.S., M.S., M.D., D.Sc., F.A.C.P., Department of Medicine, Northwestern University Medical School, Chicago; formerly Consulting Physician, the Mayo Clinic. London: J. B. Lippincott Company. 1934. Pp. 615. 21*s.*

THIS practical book contains an abundance of menus which have the virtue, not altogether common in American books, of being equally applicable to the British subject and to the citizen of the United States. It is divided into a preliminary section dealing with the principles of dietetics in health, followed first by sections on the dietetic treatment of those diseases in which food is of paramount importance and later by indications for dietetic treatment in diseases such as chronic arthritis, secondary anæmia, and the fevers in which, although important, the type of food has no specific effect. The sections dealing with each disease are preceded by a series of introductory paragraphs in which the scientific principles governing the choice of diet are discussed. These paragraphs are for the most part poor. It is unfortunate that the section dealing with obesity makes no mention of the importance of abstinence from alcohol, whilst the warning against the indiscriminate use of thyroid seems to be unduly severe compared with the succeeding paragraphs concerning dinitrophenol. The discussion of the value of salt-free diets is somewhat inadequate, whilst the section dealing with the dietetic treatment of peptic ulcer is, in our view, marred rather than helped by the preliminary paragraphs which give dangerously brief reference to the indications for surgery and the value of various alkalis. There are, however, not many books at present available which provide the practitioner with such a range of analysed diets applicable to a wide variety of medical conditions.

The 1934 Year Book of Dermatology and Syphilology

Edited by FRED WISE, M.D., Professor of Dermatology and Syphilology, New York Post-graduate Medical School and Hospital of Columbia University; and MARION B. SULZBERGER, M.D., Associate in Dermatology and Syphilology, New York Post-graduate Medical School and Hospital of Columbia University. Chicago: Year Book Publishers Inc.; London: H. K. Lewis and Co., Ltd. 1935. Pp. 704. 12*s.* 6*d.*

This valuable symposium of the world's best work in the two subjects continues to flourish and advance. It contains, among other useful features, an editorial on the modern treatment of early syphilis, which is primarily intended for the general practitioner, but no specialist can afford to ignore its precepts. These are based on reliable statistical information and conclusions obtained "coöperatively" by Stokes from among the leading venereal diseases clinics in America. Some 23 pages are devoted to a synopsis of papers dealing with mycotic infections, including the epidermophyton, actinomycosis, and blastomycosis. Ensuing sections deal with the latest work on allergy, drug eruptions, hæmatogenous dermatoses, cancers and precancerous conditions, mycosis fungoides and leukæmias, venereal diseases other than syphilis, chronic granulomata, dermatotherapy, physical therapy, experimental and investigative studies, including some important work on viruses, and finally syphilis and its treatment. The importance of this publication lies in its selection for collation and review each year of all contributions to the literature that are likely to survive. It is worthy of the support of every English-speaking dermatologist.

Parasitism and Disease

By THEOBALD SMITH, Director Emeritus of the Department of Animal Pathology, Rockefeller Institute for Medical Research. Princeton: Princeton University Press; London: Humphrey Milford, Oxford University Press, 1934. Pp. 196. 9*s.*

SHORTLY before his death, at the age of 75, Theobald Smith brought together his reflections upon the nature of infective disease, matured by half a century of work and thought, and presented them in the Vanuxem lectures as "a final attempt at showing the relation between disease and parasitism in its broadest manifestations." These lectures have now been published in a slightly expanded form. The invasion of the body of animal or man by micro-organisms is treated by Theobald Smith as a problem in biology; as a struggle for existence between two divided them into those which depended on a constitutional stimulant such as œstrin and progestin, and those which were purely local. He thought that involution was a process of degeneration and absorption. There was a sudden collapse of the whole uterus with interference with its blood-supply, leading to degeneration of the tissues of the uterine wall. He also had never seen fatty degeneration during the process of involution. He felt that Goodall's statement should be reviewed in the light of modern knowledge of hormones.

In reply, Dr. GERRARD said he thought the elastic tissues were derived from connective tissue cells. Examination of the slides left no doubt that there were differences in the amount of elastic tissue in super- and sub-involution.

Dr. GERRARD also reported a case of placenta prævia complicated by adherent meningocele.—Dr. R. NEWTON demonstrated a specimen with sarcomatous change in a fibromyoma of the round ligament. —Dr. C. P. BRENTNALL showed a radiogram of an obliquely contracted pelvis, and Dr. BAILEY showed a granulosa-cell tumour of the right ovary removed from a patient aged 62, a uterus with rudimentary horn and fibroids, and an adenocarcinoma of the cervix removed by extended pan-hysterectomy.

REVIEWS AND NOTICES OF BOOKS

The Treatment of Fractures

By LORENZ BÖHLER, Director of the Hospital for Accidents, Vienna; Lecturer on Surgery in the University of Vienna. Fourth English edition, translated from the fourth enlarged and revised German edition by ERNEST W. HEY GROVES, M.S., M.D., F.R.C.S., Consulting Surgeon, Bristol General Hospital; Emeritus Professor of Surgery, University of Bristol. Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall Ltd. 1935. Pp. 578. 42*s.*

Technique du traitement des fractures

By LORENZ BÖHLER. Translation into French of the fourth edition by M. BOPPE, Chirurgien des Hôpitaux de Paris. Paris: Masson et Cie. 1934. Pp. 653. Fr.160.

THE appearance of French and English editions of Prof. Böhler's important work has made it available to surgeons and to students of surgery throughout the world; but the significance of these translations is greater even than that, for it is a tribute to the widespread admiration felt for Böhler's work in Vienna. Dr. Boppe, the translator into French, has himself been engaged in carrying into practice in the surgical clinics of the Hôtel-Dieu the main principles taught by Böhler, and in a preface Prof. Hartmann, his chief in these clinics, speaks with satisfaction of the results obtained. Mr. Hey Groves has visited the Vienna clinic and been impressed with its methods and with the fundamental principles underlying them. Böhler's great enthusiasm for his subject, the originality of many of his ideas, and the immense amount of care he habitually bestows on the patients under his care are reflected in this work, which is a lasting monument to his hospital. The chief principles of treatment advocated by Böhler are reduction under local anæsthesia of all fractures (including fractures of the spine); immobilisation in an unpadded plaster cast; relegation of open operation to a very subsidiary position; the use of skeletal traction during reduction and application of plaster splints; standardisation of apparatus and methods so as to allow of efficient organisation; and, finally, substitution of early function of limbs and body generally for the methods of physicotherapy, particularly of massage, commonly in use.

While the book under review is perhaps primarily an account of organisation and treatment of these injuries under ideal conditions so as to ensure the most perfect possible functional results and the avoidance of all unnecessary economic waste, it is at the same time an excellent text-book on fractures. Nowhere can be found a clearer description of the mechanics involved in the displacement and reduction of individual fractures. Teaching by diagrammatic drawings has been carried to a fine art; a very great deal can be learned by study of these alone. No detail seems too small to have escaped the author's attention. He explains the reason for completely encircling the chest in fractures of the ribs, as immobilisation of one side alone is not possible when both move in unison at each respiration. The position of most ease in synovitis of the long head of the biceps brachii is illustrated by a careful series of diagrams. The apparent alteration in length of the thigh in different positions of the hip- and knee-joints is also illustrated. This is an important fact to impress on the student, but it is surely a little surprising to find the movable patella taken as the lower fixed point in testing for shortening of the femur, rather than the internal malleolus. One might also query the period of seven to eight weeks as giving sufficient union to allow of weight-bearing in a case of fracture of the shaft of the femur. Few surgeons would agree with this, especially as Böhler apparently does not use a walking calliper splint in the after-treatment. Many surgeons will be inclined to agree with Prof. Hartmann's opinion, expressed in the preface to Dr. Boppe's translation, that Böhler's prejudice against open operation is carried a little too far. Criticism of individual methods of treatment tend, however, to disappear before the intrinsic evidence of personal experience in every section of the book. Böhler wrote in the preface to the third edition that some things which he formerly advised were now relegated to the category of "mistakes." Attention is specifically drawn to these "mistakes" in the text, and this is a good illustration of the spirit in which the author approaches his subject.

The section on fractures of the spine will be a revelation to anyone unfamiliar with the results obtained by modern methods of reduction and early function. Böhler's patients are seen walking about and performing acrobatic exercises in their plaster jackets a few days after the injury. The English translation contains new material in the section dealing with fractures and fracture-dislocations of the cervical spine, and incorporates in the chapter on fractures of the femoral neck the most recent developments of the Sven Johansson technique. Some of the most interesting pages are undoubtedly those contained in Appendix D, which deals with the economic aspect of accidents and the organisation of successful hospital treatment. Both English and French editions are very fully illustrated, and the respective publishers deserve congratulation on the general appearance of the volumes. The translations are excellent.

Dental Caries

Studies in the Ætiology of Dental Caries. By G. Graham Macphee, M.D., Ch.B., L.D.S., Hon. Consulting Dental Surgeon, Liverpool Stanley Hospital; Hon. Assistant Surgeon, Liverpool Dental Hospital. London: John Bale, Sons and Danielsson. 1935. Pp. 203. 7*s.* 6*d.*

This book falls into two parts: one a summary of existing views on the ætiology of dental caries, and the other an account of some bacteriological investigations carried out by the author on the possibility of an immunological reaction in the disease. It is useful from time to time to have the literature of a disease summarised and the various theories examined critically. But this laborious task must be properly done to be of value. The summary provided in this book is too incomplete to be of much use either as a convenient source of reference or as a reasoned and critical evaluation of the data.

Dr. Macphee's description of experiments on the immunological reactions in dental caries approaches the subject from a new point of view, and demands consideration. He claims to have found a definite precipitin reaction between filtered or centrifugalised emulsions of carious dentine and serum from the same or other subjects. He finds that the intensity of this reaction is greatest in subjects immune to caries as judged by clinical examination, and least in those who show a high susceptibility to caries. Dr. Macphee suggests that this precipitate may account for the calcium barrier in the translucent zone, and that a complete reaction may result in the condition known as arrested caries. Complement-fixation tests give a positive result which is greater with antigen from carious dentine than with antigen from normal dentine. Dr. Macphee draws the conclusion that these reactions suggest that dental caries is a true infective process either due to bacteria or to a filter-passing virus. These views are opposed to much of the current teaching which regards the bacterial factor as being responsible for the formation of acid from carbohydrate fermentation, but not as being itself the causative factor. Immunity and susceptibility are usually regarded as being dependent on structural factors and the physical quality of the diet, though there is much conflict of opinion as to the respective importance of these two factors. Dr. Macphee gives a fresh orientation to a problem which continues to be one of the most baffling in dentistry, and his views will doubtless be investigated.

Treatment by Diet

By Clifford J. Barborka, B.S., M.S., M.D., D.Sc., F.A.C.P., Department of Medicine, Northwestern University Medical School, Chicago; formerly Consulting Physician, the Mayo Clinic. London: J. B. Lippincott Company. 1934. Pp. 615. 21*s.*

This practical book contains an abundance of menus which have the virtue, not altogether common in American books, of being equally applicable to the British subject and to the citizen of the United States. It is divided into a preliminary section dealing with the principles of dietetics in health, followed first by sections on the dietetic treatment of those diseases in which food is of paramount importance and later by indications for dietetic treatment in diseases such as chronic arthritis, secondary anæmia, and the fevers in which, although important, the type of food has no specific effect. The sections dealing with each disease are preceded by a series of introductory paragraphs in which the scientific principles governing the choice of diet are discussed. These paragraphs are for the most part poor. It is unfortunate that the section dealing with obesity makes no mention of the importance of abstinence from alcohol, whilst the warning against the indiscriminate use of thyroid seems to be unduly severe compared with the succeeding paragraphs concerning dinitrophenol. The discussion of the value of salt-free diets is somewhat inadequate, whilst the section dealing with the dietetic treatment of peptic ulcer is, in our view, marred rather than helped by the preliminary paragraphs which give dangerously brief reference to the indications for surgery and the value of various alkalis. There are, however, not many books at present available which provide the practitioner with such a range of analysed diets applicable to a wide variety of medical conditions.

The 1934 Year Book of Dermatology and Syphilology

Edited by Fred Wise, M.D., Professor of Dermatology and Syphilology, New York Post-graduate Medical School and Hospital of Columbia University; and Marion B. Sulzberger, M.D., Associate in Dermatology and Syphilology, New York Post-graduate Medical School and Hospital of Columbia University. Chicago: Year Book Publishers Inc.; London: H. K. Lewis and Co., Ltd. 1935. Pp. 704. 12*s.* 6*d.*

This valuable symposium of the world's best work in the two subjects continues to flourish and advance. It contains, among other useful features, an editorial on the modern treatment of early syphilis, which is primarily intended for the general practitioner, but no specialist can afford to ignore its precepts. These are based on reliable statistical information and conclusions obtained "coöperatively" by Stokes from among the leading venereal diseases clinics in America. Some 23 pages are devoted to a synopsis of papers dealing with mycotic infections, including the epidermophyton, actinomycosis, and blastomycosis. Ensuing sections deal with the latest work on allergy, drug eruptions, hæmatogenous dermatoses, cancers and precancerous conditions, mycosis fungoides and leukæmias, venereal diseases other than syphilis, chronic granulomata, dermatotherapy, physical therapy, experimental and investigative studies, including some important work on viruses, and finally syphilis and its treatment. The importance of this publication lies in its selection for collation and review each year of all contributions to the literature that are likely to survive. It is worthy of the support of every English-speaking dermatologist.

Parasitism and Disease

By Theobald Smith, Director Emeritus of the Department of Animal Pathology, Rockefeller Institute for Medical Research. Princeton: Princeton University Press; London: Humphrey Milford, Oxford University Press, 1934. Pp. 196. 9*s.*

Shortly before his death, at the age of 75, Theobald Smith brought together his reflections upon the nature of infective disease, matured by half a century of work and thought, and presented them in the Vanuxem lectures as "a final attempt at showing the relation between disease and parasitism in its broadest manifestations." These lectures have now been published in a slightly expanded form. The invasion of the body of animal or man by micro-organisms is treated by Theobald Smith as a problem in biology; as a struggle for existence between two species, between the invasive lytic and toxic properties of the parasite and the defensive activities of the host. The struggle may culminate in the compromise of harmless parasitism, or even mutually beneficial symbiosis. Disease results from a lack of balance between parasite and host: as when the common cocci leave their normal haunts in the skin and mucosa and invade the underlying tissues; or when actinomyces escapes from its vegetable host into the animal. Most epidemics and pandemics, according to the author, are probably due to "strayed parasites"—parasites invading aberrant hosts from an animal reservoir or spreading to a group of more yielding hosts of the customary species.

These examples illustrate the main burden of the book: disease as a dynamic contest between invader and defender. It is no new theme, and the author does not pretend to have included the very latest ideas, but the argument is illustrated by such a wealth of material that it provides fascinating reading—not sufficiently technical perhaps for the specialist in bacteriology, and demanding rather too much knowledge for the "student body not yet conversant with the problems of disease" for whom the lectures were primarily intended, but most stimulating for the general medical reader. The last chapter gives a brief but vivid history of the utilisation of bacteriological discoveries in the treatment and prevention of disease—largely a history of the homeric years during which the author played so distinguished a part.

Bronchoscopy, Esophagoscopy, and Gastroscopy

Third edition. By CHEVALIER JACKSON, M.D., Sc.D., LL.D., F.A.C.S., Professor of Bronchoscopy and Esophagoscopy, Temple University; Bronchoscopist, Temple University Hospital; and CHEVALIER L. JACKSON, A.B., M.D., M.Sc. (Med.), F.A.C.S., Professor of Clinical Bronchoscopy at the same University. London: W. B. Saunders Co., Ltd. 1934. Pp. 485. 37*s.* 6*d.*

IN this new edition Dr. Chevalier Jackson is joined by his son as joint author, thus assuring a family continuation of a reputation already firmly established. The arrangement of the book does not differ materially from that of its predecessor, while the illustrations retain their high level of clarity. The armamentarium has been increased, noticeably by the addition of costo-phrenic bronchoscopes, intended for the removal of foreign bodies in the finer bronchi. They are used in conjunction with a carefully designed double plane fluoroscope, elaborated with the help of Dr. Manges. It is interesting to learn that practically no foreign bodies are nowadays considered to be irremovable by bronchoscopic methods in the Temple University Clinic. Many have attempted to copy the methods used there, and some have designed fresh instruments with the intention of lessening difficulties of technique. None can hope to surpass this clinic in the care devoted to preparation, in technical skill, or in the excellence of the results obtained. The details of the team-work are apparently unaltered; no inclination is noticeable towards the use of a mechanical head-rest, an adaptation called for in clinics where the facilities are less developed. The authors themselves continue to avoid the use of general anæsthesia, but they realise that every operator must decide for himself on this question, and many will prefer to employ—in suitable cases—such merciful drugs as avertin or evipan. The authors do not appear to be impressed by the results of implantation of seeds of radon in œsophageal carcinomata, and tend rather to recommend deep X ray therapy and early gastrostomy. In this country congenital shortening of the œsophagus, associated with the presence of a thoracic stomach, has attracted considerable attention; it is not given prominence in this work.

The book gives explicit and ample directions on all points of operative technique, and on the diagnosis and treatment of diseases of the larynx, trachea, bronchi, and œsophagus; in addition, it provides much information on subjects beyond the direct sphere of peroral endoscopy.

It should be of the greatest interest to the thoracic surgeon who requires the information afforded by direct examination before dealing with such diseases of the lungs or œsophagus as fall within his province. Above all, this book, based on years of experience, is the authoritative guide for the laryngologist in every branch of peroral endoscopic work.

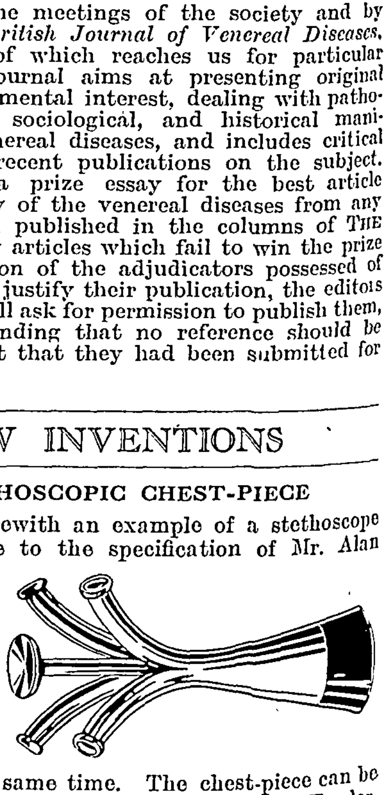
Medical Society for the Study of Venereal Diseases

THE Society aims at the bringing together those interested or engaged in the diagnosis, treatment, and public health aspect of venereal diseases. This comprehensive purpose involves a membership composed of practitioners, who are engaged not only in the study and practice of venereal diseases, but in those branches which possess interests cognate to the foregoing. For example, genito-urinary surgeons, neurologists, dermatologists, and ophthalmologists by exchanging views can give to and receive from each other enlightenment. Such an interchange is rendered possible by the addresses given and the resultant discussions at the meetings of the society and by means of the *British Journal of Venereal Diseases*, a recent issue of which reaches us for particular notice. The Journal aims at presenting original articles of fundamental interest, dealing with pathological, clinical, sociological, and historical manifestations of venereal diseases, and includes critical reviews of the recent publications on the subject. Particulars of a prize essay for the best article dealing with any of the venereal diseases from any angle have been published in the columns of THE LANCET. If any articles which fail to win the prize are in the opinion of the adjudicators possessed of such merit as to justify their publication, the editors of the Journal will ask for permission to publish them, on the understanding that no reference should be made to the fact that they had been submitted for the prize.

NEW INVENTIONS

A STETHOSCOPIC CHEST-PIECE

I ENCLOSE herewith an example of a stethoscope chest-piece made to the specification of Mr. Alan Burrows, which I have found very useful for teaching purposes. By means of this chest-piece it is possible for two persons to auscultate at the same time. The chest-piece can be procured from Messrs. Alexander and Fowler, Pembroke-place, Liverpool.



I. HARRIS, M.D.

THE LANCET

LONDON: SATURDAY, APRIL 27, 1935

SUPERSENSITIVE SKINS

CUTANEOUS inflammation provoked by irritants does not differ profoundly from the kind of reaction associated with "sensitisation"; thus primula dermatitis has much in common with chrome dermatitis, though chromic acid is an irritant and the primula plant, strictly speaking, is not. This is at the root of much difficulty and confusion in the interpretation of dermatoses, especially in industrial and medico-legal work. Theoretically differentiation should be readily possible, the one reaction being exogenic and pathological, the other personal and physiological; but in practice there is a large group of affections coming into both spheres in which it is far from easy to assess the relative importance of external irritant and internal idiosyncrasy. It is here that the patch test is likely to be helpful, and it now fills an important place in dermatology. If the suspected agent is applied for 24 hours to the skin of a number of people and if it produces no reaction in the normals but only in the patient, the information will obviously be of value; and though the patch test does not always tell us all we want to know it has the merit of being very reliable—unlike the scratch and intradermal tests which are uncertain in action.

From time to time cases of dermatitis are reported as arising from contact with nickel or chromium—metals which are not chemical irritants at all. Since the carbonate, phosphate, or chloride of chromium can be ingested or inhaled by animals without harmful effects, it must be supposed that before dermatitis is produced some degree of corrosion is necessary; the formation of oxides, sulphates, or chlorides will facilitate ionisation, and it is presumably the non-toxic metallic anion which provokes reactions in a person with specific allergic sensitiveness. Dermatitis of this type is reported from the wearing of nickel or chromium spectacles, wrist-bands, safety-pins, and suspender clips, and it appears to be essentially similar to dermatitis due to fur, hair, and fabric dyes; alkaloids like atropine; chemicals like boric acid, perchloride of mercury, picric acid, and bichromate of potash; oils; turpentine; alkalis and other common causes of allergic dermatitis. The sensitisation seems to be always epidermal and can be demonstrated by a patch test which gives a positive reaction in the susceptible subject only. The hypersensitiveness is sometimes very acute, as in the case reported in our present issue by Prof. HERCUS and Mr. PURVES, in which a youth suffering from dermatitis provoked by contact with furs containing a trace of bichromate of potash gave a positive patch test to a dilution of 1 in 100,000 of the salt. That serious industrial hazards are associated with the nickel-plating, chromium-plating, dyeing, and other chrome trades has long been recognised, but for the most part the inflammations and ulcerations of skin and mucous membranes are the direct result of gross chemical injury from chromic acid or the chromates, and any and all who are subjected to the conditions of the trades must suffer from them unless adequate precautions are taken; here the chromium is present in the kation, which is irritant by reason of its oxidising properties. At the same time there is in these trades a high incidence of eczematous dermatitis, even where intimate contact with strong irritants is avoided, and this is attributable to sensitisation to chrome or other substances encountered. We know that skin sensitiveness and occasionally asthma may follow injury from chrome dust, and the question of an association between these two types of reaction—the direct, irritant, or pathological, and the allergic or idiosyncratic—inevitably comes up. Paraphenylene-diamine is toxic by virtue of its chemical structure, and internally gives rise to serious damage which may prove fatal: has this any bearing on the fact that a very small proportion of people coming into contact with paraphenylene-diamine on a fur will give an allergic response to its presence? Bichromate of potash as a solid will provoke an ulceration of tissues in all who handle it, whereas only a few have an allergic sensitiveness to it in ordinary solutions. Such sensitiveness may be shown to a great variety of substances, many of them quite harmless but some definitely irritant in strong concentrations, such as iodine and perchloride of mercury; and it may be that the natural toxicity of a substance has some relation to the ease with which it provokes an allergic response. Evidence can be found in favour of this contention, but even if it is correct we must still take account of constitutional difference between the allergic and the normal subject—a difference often apparent on examining the patient and his past and family history. JOULES,[1] in recording a case of asthma due to chrome sensitisation, suggested that the disease may have been provoked by a heavy initial exposure to the irritant; and it is probable that such "massive dosage" helps to produce skin sensitisation also. The incidence of dermatitis in the chrome industries lends some support to this idea, as does BLOCH'S demonstration that repeated application of a concentrated extract of primula will provoke sensitisation in anyone. HAXTHAUSEN[2] succeeded in inducing sensitiveness to perchloride of mercury by the intradermal injection of this substance mixed with a little of the subject's own serum, and for several weeks a positive patch-test reaction could be evoked. Likewise desensitisation can sometimes be performed; for example, WALLER[3] has managed to desensitise patients suffering from atropine dermatitis by the injection of atropine combined with the protein of tears. The desensitisation was not always long-lived but it was of real practical value.

Much remains obscure about these phenomena, and the discovery of a specific exciting cause may solve only part of a patient's problem. The allergic subject may pass from one trade to another and present the particular dermatoses of each. Not only so, but he may quite conceivably develop a specific allergic sensitiveness to some external agent by reason of psychological trauma, the dermatosis being an associated reaction of the conditioned reflex type.

THE STOMACH AND THE SOUL

ELSEWHERE in this issue we publish a lecture by Dr. GEORG WOLFF of Berlin, whose medical-statistical researches are favourably known to his colleagues in this country, which starts a train of reflections. In these days of international tension, it is imprudent to make *any* comment upon the condition, moral or physical, of a foreign country. *But it is perhaps not unduly bold to* say that, throughout the period Dr. WOLFF has studied, the economic state of Germany was less favourable—or more unfavourable—than that of England. Those who still believe that Germans are better organisers than English may urge that Germany has made more skilful use of her inferior resources than we should have done. But nobody can seriously maintain that 1924–32 was a time of prosperity in Germany. Yet, as Dr. WOLFF shows, there has been throughout that gloomy period a steady improvement in the physique of urban children. Whether we adopt his anthropometric criteria or the evidence of mortality-rates, it appears that the German people are physically better off than in times to which some of their leaders look back as to a Saturnian age. *De te fabula narratur.* It might not be difficult to select particular observations within the field of public hygiene in our own country which give reason for apprehension. We have no doubt that Dr. WOLFF could also select from German experience some features which are unpleasing. But in England, as in Germany, a general survey of the public health is reassuring. Some have criticised the utterances of that eminent public servant, Sir GEORGE NEWMAN, on the ground that he has put too favourable a complexion upon the facts. The criticism is based upon a confusion of thought. Great evils still exist but, from the physiological point of view, general improvement is manifest. Indeed it may well be that this improvement itself is a principal factor of modern discontents. Almost a century ago a now forgotten author wrote :—

> "It is a popular saying, that hunger will break through stone walls, by which it is implied, that its calls are not to be resisted and that the most difficult obstacles will be overcome to satisfy it. This may be true of hunger induced by sudden fasting occurring to persons in good health, but it is very far otherwise when an individual is suffering gradually and becoming exhausted by slow degrees, from a long continued deficiency of food or the use of a very impoverished diet. In such cases, when the health begins to decline, mental obtuseness and diminished sensibility follow: all the sensations are blunted, and the feeling of hunger being feebly experienced, no very strenuous efforts are made to allay it." (R. B. Howard: An Inquiry into the Morbid Effects of Deficiency of Food. London, 1839, p. 28.)

This may be generalised. The physiological level of the peoples of West European nations has been raised ; the proportion of men and women who are too immersed in a struggle for bare existence to be able to reflect upon the contrast between the actual and the desirable has decreased. Thus we have a broad basis for discontent, divine or otherwise. As THE LANCET has so often urged, it is the psychological aspect of good health and bad health which urgently needs study. We may reasonably be optimistic as physicians of the body; as physicians of the soul we cannot look on the present or foresee the future with equanimity.

SNAKE VENOM IN THERAPEUTICS

USEFUL remedies may be extracted from the most unpromising materials, and even the reptilian venoms are now being turned to profitable use. Some time ago the treatment of epilepsy by colubine venoms was advocated in South Africa by F. W. FITZSIMONS, but it is difficult to assess its value from the few reports of cases so dealt with. MONAELESSER, in 1929, instituted the use of similar venoms as a local analgesic in cases of carcinoma, with reported success. Recently advantage has been taken by R. G. MACFARLANE and BURGESS BARNETT of the extremely powerful coagulant present in Russell's viper venom; it has been used with success as a local hæmostatic in cases of hæmorrhage in hæmophilic and other subjects.[1] A subsequent paper by S. M. PECK and N. ROSENTHAL[2] appears to establish a further venom as a therapeutic agent; they publish a report of 40 cases of hæmorrhagic diathesis treated by injections of the venom of the moccasin, a North American member of the crotaline species. They were led to this line of treatment by the observation of PECK and H. SOBOTKA[3] that a state refractory to the Shwartzman phenomenon could be produced by injections of vascular poison, moccasin venom being the most efficient. The Shwartzman phenomenon consists in local hæmorrhagic necrosis following the injection of certain bacterial filtrates. Its suppression by small amounts of a venom capable of producing hæmorrhages when given in larger quantities might suggest an immunity reaction. That this is not the mechanism, however, is shown by the fact that antibodies could not be demonstrated in the blood of animals so protected, and that antivenin had no effect on the Shwartzman phenomenon.

The possibility that the venom has some effect upon vascular tissues therefore becomes more probable, and on this assumption it was applied to cases in which these structures were considered responsible for the hæmorrhages experienced. The venom was given intradermally, or subcutaneously, as a 1 in 3000 solution, the usual initial dose being 0·4 c.cm., working up to 0·8 or 1 c.cm. in bi-weekly injections. Some cases developed a sensitivity and required de-sensitising. The first group of the reported cases consisted of five patients with an "idiopathic" tendency to bleed frequently from the nose, mouth, and gums, there being no discoverable abnormality of the blood or tissues to account for this condition. The group included also two cases of bronchiectasis with a liability to profuse and frequent hæmoptysis. After a few injections of venom, all these patients showed an almost complete cessation of bleeding over a period of several months. Eight women suffering from severe menorrhagia, with no definite organic cause, are said to have benefited very considerably from injections of the venom, though these had to be continued for a considerable time. A series of ten cases of "toxic, anaphylactic, or endocrinal purpura" was also treated. In these cases the blood picture was normal, and the appearance of ecchymotic or purpuric spots was the principal abnormality. Two patients showed no response, but in the remainder remarkable success was achieved. Four with Osler's disease (hereditary hæmorrhagic telangiectasia) also received treatment, and all of these were reported to show improvement with diminution of the telangiectases in three of them. The response of patients suffering from thrombocytopenic purpura was less encouraging. Four failed to make any improvement, and, though four recovered completely, it is, as the authors point out, impossible to ascribe this recovery to the action of the venom with any certainty. Five patients showed improvement, however, and it is interesting to note, from the point of view of the ætiology of the condition, that this improvement was not accompanied by a rise in the platelet count, nor by a decrease in the bleeding time. Three cases of hæmophilia were treated. As might be expected, no beneficial effect was produced.

---

[2] Jour. Amer. Med. Assoc., March 30th, 1935, p. 1066.
[3] Jour. Exp. Med., 1931, liv., 407.

Reviewing this work, it becomes apparent that the best results were reported in the patients having no ascertainable alteration in the blood, or in its clotting processes. The mechanism of persistent hæmorrhages in such cases is obscure, but the fault seems to lie in the tissues that contain the blood. Thus the "idiopathic" bleeders, the cases of telangiectasia, menorrhagia, and those of non-thrombocytopenic purpura, were reported to do very well when receiving venom. Moccasin venom in small amounts has no effect on the coagulation of the blood in vivo. Its failure in hæmophilia is therefore not surprising. In this condition it is almost certain that the tissues and vessels are normal. The fact that in the cases of thrombocytopenic purpura the results of this treatment are conflicting is of interest in view of the divergence of current theories on the ætiology and mechanics of this condition. It appears that this venom exerts some influence upon the vascular tissues, resulting in a decrease in their permeability, or liability to toxic damage, and it is in cases where such factors play a part that it is useful. Quite apart from the clinical advance claimed by PECK and ROSENTHAL, their work raises many important theoretical questions, and should open up a line of investigation which should prove of value to those studying the hæmorrhagic diathesis.

A STORY OF PUBLIC HEALTH PROGRESS

SIR ARTHUR NEWSHOLME has done well to publish these reminiscences [1] of his long life of distinguished public service. The period covered by the present volume was one of great developments in preventive medicine. Changes of basic importance were made in our ideas of the causation of disease and were reflected in new administrative methods designed to express the new ideas in terms of preventive activity. In these developments the author of this book has played an important part; it is not too much to say that it is largely due to the influence he has exercised during the last fifty years that our system of public health administration has reached its present position.

NEWSHOLME's recollections go back to his native village, the Haworth of the Brontës, in the 'sixties, where he talked with people who had known the three gifted sisters and with the village druggist, an old woman, who had seen Bramwell Brontë's determined attempt to justify his boast that by force of will he would die standing. And we read that there were remarkable folk in Haworth before the Brontës, notably the Rev. W. Grimshaw, a former vicar, who on occasion did not hesitate to use a horsewhip to induce his parishioners to attend church. From Haworth the author, after a year as apprentice to a Bradford general practitioner, proceeded to St. Thomas's Hospital, where as a dresser he saw the early use of the carbolic spray and had as a fellow student and friend Kanehiro Takaki, destined to free the Imperial Japanese Navy from beri-beri. Among his teachers were Bristowe, then health officer for Camberwell, and Murchison; and he gives a vivid account of the last clinical lecture delivered by Sir John Simon, whom 32 years later he was to succeed as medical officer to the Local Government Board. In the final M.B. examination he was examined by Matthews Duncan, who had recently been appointed obstetric physician to St. Bartholomew's, and who was wont to give his pupils an admonition which, if generally adopted at the present time, would do much to reduce maternal mortality: "Never hurry, except in one circumstance—when you are trying to catch a flea." The author approached public health through general practice, and still retains the clinical outlook—an important qualification for an administrative health officer. In 1883 he was appointed M.O.H. of Clapham (a part-time appointment) where for two years he had been a general practitioner, and in 1888 took up his first whole-time post—that of M.O.H. of Brighton—which he held until his appointment in 1908 as medical officer to the Local Government Board.

The period he now reviews saw fundamental changes in epidemiological theory and practice.

---

[1] Fifty Years in Public Health. By Sir Arthur Newsholme, K.C.B., M.D., F.R.C.P. London: George Allen and Unwin Ltd. 1935. 15s.

At the beginning both were dominated by the doctrine promulgated by Chadwick and Southwood Smith, that not only does "dirt produce disease," an important but incomplete generalisation, but that effluvia from organic filth are capable of producing fevers. The author accords the chief credit of displacing the effluvia theory by a more scientific ætiology to John Snow, a London anæsthetist, and William Budd, a Bristol physician, who by personal investigation of cholera outbreaks showed that epidemic diseases are due to specific agents that multiply in the body and are communicated from one person to another :—

> "To Budd and to Snow, England is profoundly indebted. Eventually they swept away the older view that without discrimination, sanitary defects, with resultant respiratory and excremental contamination of the air determine respiratory and intestinal diseases. While not minimising the importance of these auxiliaries, they placed in its correct supreme position prevention of specific contagion as the direct aim of sanitary effort, the general removal of filth taking its place as an essential part of the effort to this end."

The general acceptance of these views, which was long delayed by the prevailing influence exercised by Max v. Pettenkofer with his emphasis on the importance of ground-water levels, led to the modern triumphs of preventive medicine. Not only has environmental "sanitation" become much more definitely directed and effective, but great advances have been made in the field of personal hygiene. The story of this progress is unfolded by the author with a freshness of outlook and a wealth of anecdote and reminiscence that make his narrative very much alive. He tells how the notification of tuberculosis in this country began, on a voluntary basis, in Brighton in 1899, and how he showed that shell-fish may convey the infection of typhoid fever—a service that brought upon him much local obloquy, which was dispelled when an oyster supper was followed by several cases of the disease including that of the chairman of the health committee, who came under the author's care as a patient in the municipal fever hospital. He tells also of researches into the ætiology of rheumatic fever, diphtheria, and summer diarrhœa; of numerous "excursions in statistics"; and of pioneer work in school hygiene and maternity and child welfare. He holds "that only after studying how public health—or any other science, theoretical or applied—has come to be what it is can one fully understand its present position, and prepare for further advance with a minimum risk of mistakes."

This volume deals chiefly with events up to 1908, when the author was appointed medical officer to the Local Government Board, and it is to be followed by one dealing with the progress made in public health while he was working at the centre. It was then that antituberculosis work was begun on a national scale, that the movement for the control of venereal disease was initiated, and that Government grants were first made available in aid of local maternity and child welfare work. All these measures were introduced on the initiative of Sir ARTHUR NEWSHOLME, whose second volume will be awaited with general interest.

ANNOTATIONS

TRANSMISSION OF POLIOMYELITIS TO MICE

THE investigation of human diseases of virus ætiology is peculiarly dependent upon animal experiments and the rate of progress is, to a large extent, governed by the species of animal susceptible to infection. The success apparently obtained by Brodie and his collaborators in transmitting anterior poliomyelitis to mice[1] opens up new avenues of approach to its experimental study, which hitherto has necessitated the employment of monkeys. Primary infection in mice was obtained by giving short X ray doses daily for ten days and then inoculating them, both intracerebrally and intraperitoneally, with virus obtained from monkeys. After an incubation period of 11 days or longer, a number of the animals showed ruffled hair, ataxia and dragging of the hind limbs; some of them died. Thereafter the disease could be transmitted serially through mice by intracerebral inoculations of infected brain tissue without the preliminary X ray treatment. With succeeding passages symptoms became more definite and the incubation period shorter, whilst the infectivity of the brain tissue increased. Thus, by the fifth passage, a 10 per cent. suspension of infected brain produced the disease, with an incubation of three days, in all the mice inoculated, whilst twelfth passage brain was infective in a dilution of 1 in 1000. The authors refer to "fixed" virus giving rise to an acute clinical picture and death within a few hours of the onset of symptoms. The "fixed" virus was also infective when administered intranasally, the incubation period being five to six days.

The lesions in mice were predominantly in the brain and meninges, in contrast to the spinal cord localisation in man and monkey. However, although virus was found in greatest concentration in the brain, it was distributed throughout the cerebro-spinal axis. The virus etiology of the mouse disease was shown by the successful infection of both mice and monkeys with bacteria-free filtrates, the latter species exhibiting "typical poliomyelitis."

The authors give a convincing summary of evidence in support of their claim that the mouse virus is the virus of poliomyelitis. Thirteen monkeys were infected with the mouse strain; the spinal cords of 4 of them were examined and showed the characteristic histopathological picture. Virus obtained from one of the 13 was first passed through another monkey and then successfully transferred back to mice. Convalescent human serum neutralised the virus and protected a monkey against infection. The virus was also neutralised by convalescent monkey serum, but not by normal monkey serum. It is emphasised that the mouse disease differs both clinically and histopathologically from Theiler's mouse encephalomyelitis.[2] A fuller report of this work and its logical extensions will be awaited with interest, especially details concerning the cross transference of virus between mice and monkeys and the immunological relationships between mouse and monkey strains. The authors already envisage a practical application of their discovery in the determination of the most suitable human subjects for prophylactic immunisation by the titration of human sera in mice.

A PSYCHONEUROTIC CLINIC

THE annual meeting and luncheon of the Institute of Medical Psychology on Monday of last week gave opportunity for a review of the work done during the 15 years since the Institute was founded in Tavistock-square. One notable change is the increase in the proportion of children who come for treatment. Of the new patients last year more than a third were children, and most of the speakers expressed their full satisfaction at this development. Lord Allen of Hurtwood especially saw in the new attitude of medical science to mental health the augury of good hope for the future. Anxiety, he said, is an all-pervading characteristic of our time, and for the maintenance of democracy it was essential not so much to improve the machinery of government as to ensure the mental health of the electors. Dr. Rees in a very informative address referred to the lesson of Dr. J. L. Halliday's inquiry into psychoneurosis as a cause of incapacity among insured persons in Scotland. Behind such diagnoses as anæmia, debility, gastritis, lay mental illnesses, in the main states of anxiety; on a conservative estimate a third of the group investigated were suffering from psychoneurotic disorders. Dr. Rees reiterated his belief that something over 60 per cent. of their patients were permanently relieved or cured. He lamented that the results were not as good as this in cases referred by the courts; the man who comes for treatment of his own free will will certainly, he remarked, do better than the man who regards his treatment as part of his sentence. There is still far more work of the kind to be done than can be done with the available staff at the Institute, although some 60 doctors put in 17,000 hours of work last year—which, as the hon. treasurer remarked, would have cost over £50,000 at Harley-street rates. Actually the payment per patient works out at about 2*s.* 6*d.* per attendance. A source of pride to the Institute is its recognition during the year by London University as an authorised centre of teaching for the diploma in psychology. Sir Henry Brackenbury in announcing this fact coupled with it the hope of a definite association of the Institute with the new Postgraduate Medical School at Hammersmith. The Institute was, he said, in a position to supply a peculiar need in this branch of post-graduate education.

PROSTATECTOMY WITH CLOSURE

IN the hands of its originator suprapubic prostatectomy with closure has been conspicuously successful. Thus in his latest paper,[1] summarising the results he has had in the four years since its introduction, Mr. Harris is able to report 556 cases with a mortality of 2·7 per cent. and without a single instance of post-prostatectomy obstruction. Although primary closure of the bladder is one of the advantages of the operation, it must not be regarded as an essential. Indeed there are certain cases in which it should not be attempted—cases in which the surgeon is not wholly satisfied that hæmorrhage has been controlled by suture, or in which the pre-operative cleaning has not proved entirely efficient. Since complete hæmostasis depends on the efficiency of the suturing, it must follow that the greater the experience and skill of the operator, the larger will be the proportion of cases in which he can perform complete closure, and in the last 100 operations performed by Harris there were only 2 in which it could not safely be carried out. A modification of the technique of "retrigonisation" or reconstruction of the floor of the prostatic urethra has been introduced. The point of entry of the boomerang needle carrying the posterior suture is now well down behind the inter-ureteric bar and usually at the deepest part of the bladder emerging in the floor of the prostatic cavity, and the bite of the needle now includes, with ease and certainty, a portion of tissue much wider and deeper than was included when the point of entry was at the base of the trigone. Another result of widening the scope of the posterior suture is that the special forceps hitherto employed at this stage of the operation are now rarely if ever required.

Originally condemned in this country, Harris's technique has been adopted by many British genito-urinary surgeons during the last year. Though unlikely to be used as a routine, it seems to be gaining an important place in prostatic surgery.

DOSAGE OF ASCORBIC ACID

A FEW weeks ago Dr. A. D. C. Bell and Dr. Wilfrid Sheldon reported the successful use of synthetic ascorbic acid for the cure and prevention of scurvy,[1] and it was suggested that these must be the first records of the treatment of human beings with a synthetic vitamin. This is probably true, but the use of the pure substance, ascorbic acid, as prepared from natural sources, dates from 1933.[2] Poul Schultzer's patient was an adult, who received 40 mg. daily intravenously for ten days, followed by the same dose every other day for ten days, while L. G. Parsons gave a nine-months' infant 40 mg. daily by mouth for eight days, and 20 mg. for another six. Both made good recoveries. In the following year, 1934, the German medical weeklies published the cure of another adult with a daily dose of 100 mg. (Bauke [3]), and of several babies (six to thirteen months) with daily doses of 30–60 mg. orally.[4] Svensgaard [5] recorded the cure of two infants, in a week and a fortnight, with 30 mg., also by mouth. How far it is an advantage to use ascorbic acid rather than orange or lemon juice is doubtful, but in face of actual scurvy the clinician is likely to prefer a standardised product, which creates no disturbance and can be injected—especially as it can now be produced very cheaply. Evidently a daily dose of 30 mg. will cure an infant though possibly 50 mg. would bring more rapid relief—a matter of some importance in a disease which causes so much suffering. The work of L. J. Harris and S. N. Ray [6] incidentally threw light on the infant's probable total requirement of ascorbic acid; for they found that the average amount in milk from 13 women was 0·056 mg. per c.cm., and since a breast-fed infant takes round about 600–1000 c.cm. of milk daily and almost never develops scurvy, it must be assumed that 30–60 mg. of ascorbic acid daily provides a margin of safety. A. Szent-Györgyi [7] estimated the infant's daily requirement at probably about 25 mg. Sheldon's case of a child with cœliac disease, which was protected for six months when receiving only 5 mg. daily in supplement to a diet thought likely to produce scurvy, cannot be taken as conclusive evidence that so small a dose is adequate, since the diet was not wholly devoid of vitamin C, and six months might not be long enough to reveal a partial deficiency. As regards the adult requirement there is much less evidence. Schultzer's patient was cured with 40 mg. daily, administered intravenously, and Bauke's with 100 mg., also injected. F. J. Göthlin,[8] who has inquired into the prevalence of latent scurvy in Scandinavian countries, suggests 27 mg. as the daily requirement for a 60 kg. man. It would be valuable if cases of scurvy in adults—now fortunately seldom seen—could be used for the accurate ascertainment of the adult minimum dose.

C. L. A. CHAMPETIER DE RIBES

THE name of Champetier de Ribes, who has just died at his home in France, is one which several generations of medical students associate with obstetrical devices. Born in 1848, he came of a distinguished legal family, one member of which was Minister of Pensions in a recent French cabinet. His medical career began in Paris with his appointment as a hospital intern in 1875, and four years later he produced a doctorate thesis on the extraction of the fœtal head through a contracted pelvis. The movements there described—since known as the Champetier de Ribes' manœuvre—proved of great value at a time when obstetrics was less surgical than it is to-day. The Champetier de Ribes' bag, made of canvas and covered with gutta-percha, came to displace the too fragile and elastic rubber bags previously employed for the dilatation of the cervix, and has been widely used in the treatment of placenta prævia.

A CARDIAC GLUCOSIDE

ATTENTION has lately been drawn to a glucoside obtained from the plant *Thevetia neriifolia*, growing in tropical or subtropical climes. It has long been known that the kernel of the nut (the bee-still nut) of this plant is poisonous, and chemical studies of its action were made last century. A clinical investigation of its digitalis-like action is now reported by H. L. Arnold, W. S. Middleton, and K. K. Chen.[9] First it was found that in men with apparently normal hearts doses of one to five cat-units given in aqueous solution by mouth reduced the pulse-rate by 9 to 20 beats per minute within two or three hours; the extent of the fall in rate was not strictly proportional to the size of the dose. Intramuscular injection likewise caused slowing of the heart but gave rise to pain at the site of the injection. Tests were then made on 23 patients with severe cardiac failure, using both intravenous and oral routes of administration, and it was shown that the heart-rate was slowed both in auricular fibrillation and when the rhythm was normal. The extent of the slowing was very variable but the possibility of causing a reduction of 30 to 40 beats per minute within 15 to 40 minutes of the injection of five cat-units was demonstrated both with regular rhythm and fibrillation. Improvement, both objective and subjective, was noted in some cases and digitalis effects could be maintained when thevetin was substituted for digitalis. The electrocardiogram usually showed changes similar to those produced by administration of digitalis—namely, increase in the auriculo-ventricular conduction-time and depression of the T-wave and the R–T interval. In some cases extrasystoles appeared to be caused by the drug. Adverse effects were observed on gastro-intestinal system as well as heart, but the anorexia, nausea, vomiting, abdominal pain, and diarrhœa which sometimes developed were commoner after the tincture of thevetia given by mouth than after intravenous injection of an alcoholic solution of the glucoside. Serious disturbance of intracardiac conduction was observed in one patient; and another died suddenly within a few minutes of an intravenous injection of thevetin. It appears that in this case the extent of previous digitalisation was uncertain.

Biological assay has shown thevetin to be one-seventh as toxic and one-seventh as potent as strophanthin. The clinical studies of Arnold and his co-workers indicate that on intravenous injection it has an action similar to that of digitalis, but more quickly developed. Also the conspicuous slowing of the heart in normal rhythm is a promising property. It is clear, however, that much more clinical experience will be needed to establish its exact place, if any, in therapeutics. It may or may not prove to have some advantages over the tried cardiac glucosides; but judging by Arnold's results the announcement that it is a most valuable cardiac remedy seems to have been premature.

ALL ABOUT HOSPITALS

THE fifth annual issue of the "Hospitals Year Book" reaches us this week. It is a comprehensive record of the voluntary hospital system, and in a sense the year book is the system, for under the auspices of the British Hospitals Association and of the Joint Red Cross Council the Central Bureau of Hospital Information (of which Mr. A. E. Ceadel, F.S.S., is secretary) has been doing work which will help more than any other single factor to perpetuate the existence of this system. It is the intention of Mr. R. H. P. Orde, who is hon. secretary of the Association and editor of the Year Book, that the voluntary system of hospitals should reach a degree of administrative excellence equal to that attained medically and surgically. One of the objects of the Association is to create machinery by which such a result may be made possible. The survey of statistics furnished by the voluntary hospitals themselves is increasingly complete; there was in the year under review a surplus of £923,000, receipts over expenditure, in the hospitals of Great Britain and Ireland, an amount £176,000 in excess of the previous year; but in his financial review Sir Charles Harris indicates the danger signal in hospital finance, which is deficit in maintenance account. There was in the year a deficit of £252,000 on the working of a group of 267 hospitals; this group includes a third of the London hospitals and a quarter of the hospitals in the rest of the United Kingdom. Legacies continue to shrink, and there is an increasing tendency to earmark them for special purposes. There is a strong feeling on the part of hospital administrators that the State should not intercept at the source one-tenth of all sums bequeathed for the benefit of the sick. As long ago as 1923 an influential deputation waited upon the financial secretary of the Treasury without success; while it may be true that a government grant would discourage voluntary gifts and depress the voluntary system it seems certain that the indirect assistance afforded by exemption from legacy and succession duty would encourage it. To balance the maintenance account a concerted move is being made to check waste on purchases. One objective of the Bureau is to bring users and producers into effective contact; it now makes the practical suggestion that a new article should be tried out by a group of say half a dozen hospitals which should then give the others the benefit of their experience. Otherwise it might easily happen that a new article might be tried by 50 or 100 hospitals and eventually discarded as unsuited for its purpose. Purchase in bulk last year saved one county council more than £8000 in the cost of provisions, drugs, and clothing, an example of economy without detriment to the objects of hospital care. Little need be said about the directory of voluntary hospitals which is year by year more complete and informative. It is not possible to say quite the same of the directory of municipal and public assistance hospitals, for a casual glance makes it evident that the hospitals which have not yet been appropriated by public health authorities but are still under the public assistance committees do not appear in the directory. Some of these hospitals, although nominally institutions, are as large and as well equipped as any of the non-teaching voluntary hospitals. To take a single example, the Romford Institution under the Essex County Council is a modern hospital with accommodation for over 800 patients, a visiting staff of seven well-known consultants, and surgical assistants for whom the qualification of F.R.C.S. Eng. is demanded. No survey of hospitals in this country could be considered complete without them, but there is no work of reference—not even the Medical Directory—in which they are included. It is an illustration of how little the intention of the Local Government Act of 1929 is yet appreciated that in 1935 there should still be hospitals in a sort of no-man's land. The Year Book may be obtained from the Joint Council House, 12, Grosvenor-crescent, London, S.W.1, at the price of 10*s*.

A USE FOR SEIZED NARCOTIC DRUGS

THE Permanent Central Opium Board held its twenty-third session at Geneva on March 25th–29th and L. A. Lyall, the British representative, was unanimously re-elected chairman. A question arose as to what should be done with contraband dangerous drugs that had been confiscated and whether the export of such seizures should be regarded as permissible under Article 18 of the Limitation Convention of 1931. The Board noted with satisfaction the recommendation of the Advisory Committee on Traffic in Opium to the effect that " seized drugs, if not destroyed or converted, but reserved for medical and scientific use within the meaning of Article 18 of the Limitation Convention should be devoted to the requirements of hospitals and scientific institutions or incorporated in Government stocks." In view of the magnitude of the seizures in some countries it is well to have this definite ruling and thus finally account for this illicit surplusage of supply. The Board has again had occasion to call attention to the insufficient statistical information furnished by some of the States which are parties to the several conventions; in particular several of the Central and South American countries have been in default in this regard. The investigation by the Board into discrepancies between reports received led to the discovery in one case of a forged certificate for import, and in another case that a legitimate order had been stolen in course of transit. The next meeting of the Advisory Committee on the Traffic in Opium and other dangerous drugs will be held in Geneva on May 20th, when no doubt attention will be called to the accusation, made before a special court in Cairo, that several doctors, a chemist, and some male nurses have been implicated in illicit traffic in dangerous drugs.

HOMŒOPATHIC TREATMENT OF FEVERS

IT appears that the corporation of Glasgow has given its medical officer of health a free hand to experiment with the treatment of cases of infectious disease by homœopathic methods in the city hospitals, if he so desires. The proviso was made, no doubt, in the knowledge that a local authority or the governors of a hospital have no legal responsibility for the results of treatment. Their duty ends when they have exercised reasonable care in appointing their professional staff (Evans *v.* Corporation of Liverpool, 1906, 1 K.B. 160; Hillyer *v.* St. Bartholomew's Hospital Governors, 1909, 2 K.B. 820; and Foote *v.* Shaw Stewart, 1912, S.C. 69). Obviously, if a medical officer has to bear the brunt of any claim for damages arising from the mode of treatment he has adopted, the decision as to the nature of that treatment must be left to his own judgment. Apart from any question of lay dictation, which does not appear to arise in the present instance, it must be remembered that the medical officer of health of a large city is an administrative officer. While he is generally responsible for the conduct of the medical staff engaged in clinical work, he is hardly in a position to supervise or dictate their clinical methods. Indeed, any attempt on his part to do so might justifiably be met with the retort that he must conduct and personally take full responsibility for the treatment of the individual patients by any methods which he personally wishes to be submitted to investigation. This would be impracticable. It would seem that, in the case of homœopathy in Glasgow, there is no attempt to compel the medical officer of health and his colleagues to try out homœopathy, and probably if they refuse to take the responsibility the council will appreciate their reasons; but, if they desire to please the majority who evidently wish to see it tried, the only safe course is to ask the corporation to take the responsibility themselves of appointing a homœopathist, or a team of homœopathists, for a sufficient period to make the experiment worth while.

So far as some of the infectious diseases are concerned, such as scarlet fever, it is probably true that it matters very little what form of therapy is administered, so long as the nursing and general care of the patients is adequate. To a certain extent this may be true even of such a fatal disease as typhoid. But scarlatina is now so mild and typhoid is now so rare in this country that it might take a very long time to determine the result of any experiments in their treatment. On the other hand, the application of the principles of homœopathy, if we understand them correctly, to the treatment of diphtheria, cerebrospinal fever, and, to a certain extent, pneumonia, would be contrary to the whole trend of present-day medical opinion, which is all in favour of specific serum therapy. These diseases are comparatively lethal and any departure from orthodoxy in treatment might have serious results. Yet it would be unscientific to select the diseases or the patients to be submitted to an experiment of this kind. If an investigation into the merits of homœopathy were to be conducted in a public hospital, it would appear to be necessary for the public to be informed by the medical officer of health that its methods are contrary to accepted medical opinion and that he and the medical superintendents of the hospitals will take no

Dr. Robert Hella Library

responsibility for the results. If, on the other hand, the homœopathists maintain that, in the use of specific sera, they differ neither in principle nor in choice of reagents nor in their dosage from their medical colleagues, an experiment would serve very little purpose although it would probably be free from risk.

It may be that the corporation of Glasgow have received some assurance on these points. If they have, there is an easy way out for the medical officer of health, but a concession, which is itself not undesirable, would not be likely to lead to any practical conclusion as to the real merits of what is genuinely described as homœopathy. Perhaps the majority decision of the corporation is to be welcomed as indicating its appreciation of the benefit which may result from scientific investigation in its hospitals. The output of research from the fever hospitals in Glasgow and elsewhere has been considerable in the past. Perhaps it would have been greater if the hospital doors had been opened wide to research workers not definitely on the resident staffs. Any extension of this kind, which would not seriously interfere with hospital administration or the well-being of the patients, would be all to the good, but these conditions are essential, and, where patients are concerned, their sanction or that of their parents for any serious departure from accepted methods of treatment is desirable.

A COURT PHYSICIAN

Dr. Norbert v. Ortner was physician to the Emperor Francis Joseph and the last of the great Viennese clinicians. He had only just reached his seventieth year but had resigned his chair as director of the Second Medical Clinic some years ago on account of bulbar paralysis, and it is pathetic that he should have suffered for so long from a disease which he had himself often demonstrated to his pupils as incurable and of unknown ætiology. Ortner was a native of Linz in Upper Austria, and as a student developed a keen faculty of observation with a leaning towards pathology. Quite early he published two little books, one on congenital disease of the aorta, the other on mixed infection in pulmonary tubercle, and it was these, especially the latter, which attracted the attention of Neusser, who offered him an assistantship in his clinic. This was in 1893 and was the beginning of Ortner's career as a clinician. He spent his whole working life practising and teaching in Vienna, except for four years when he held the chair of medicine at Innsbruck, from which he was recalled in 1911 to succeed Strümpell as chief of the foremost medical clinic in Vienna. His writings included a contribution to infections of the bile-ducts, which brought him the Bamberger scholarship, studies of various valvular diseases of the heart, and a monograph on dyspragia intestinalis; but he is best known by his book on Pain and his great work on the Therapeutics of Internal Diseases which was translated into nearly every European language. Ortner was a rapid worker, with an insight into the psychology of the patient which often enabled him to make devastatingly correct diagnoses. His advice was sought by patients from all parts of the world. He tells the story of his life in the fourth volume of the series of medical autobiographies brought out some years ago by his colleague, Prof. L. R. Grote, and it is from this[1] that we take the characteristic portrait. In his self-study Ortner insists that the laboratory must always be the welcome and indispensable helpmate of bedside teaching, but he followed his teacher, Neusser, in regarding the laboratory bench as the means to an end. The clinician's motto must, he said, always be "Übers Laboratorium dauernd zur Klinik."

AGAINST TRACHOMA

The International Organisation Against Trachoma, formed at Geneva in 1930, met in 1933 at Madrid and in 1934 at Paris, when reports were presented from various countries dealing with the origin and prevention of the disease. At its recent meeting in London, the Hungarian ophthalmologist, Emile de Grósz, referred in his presidential address to advances made in Japan and Poland, Algiers and Tunis, and, above all, in Egypt. He announced that A. F. MacCallan, to whose efforts during 20 years the measures to combat trachoma in Egypt are mainly due, was elected chairman for the next cycle. There is still very much to do, he said, but the new chairman will be reinforced by old tried friends, among whom he specially mentioned Morax, the editor of the *Revue Internationale du Trachome*, De Lapersonne, president of the Association Internationale de la Cécité, and Wibaut, of Amsterdam, general secretary of the organisation. So far as the British Empire is concerned, the position is covered by MacCallan's report to the Paris meeting.[2] In parts of the Indian Empire—e.g., Punjab, North West Frontier, and Baluchistan—trachoma is universal, whereas at Simla, on the foothills of the Himalayas, it is comparatively rare. The disease in India is mild and not subject to the explosive outbreaks due to superadded infection seen in Egypt and Palestine. Uncomplicated trachoma is not a cause of blindness except as the result of dense pannus; the corneal-disintegrating factor is the bacterial infection. No universal scheme of prophylaxis has been devised which is suitable for all countries, but MacCallan insists that treatment should begin in the schools.

The King has consented to open the new British Postgraduate Medical School at Hammersmith on Monday, May 13th. He will be accompanied by the Queen.

A GIFT of £10,000 has been received by the treasurers of the rebuilding and endowment fund of St. George's Hospital, with the condition that the name of the donor should remain anonymous. The gift is spread over seven years, and as the income tax rebate accrues to the hospital it will be enhanced by some £2000.

The personnel of the committee appointed by the Home Secretary to advise him on the best methods of developing the Metropolitan Police Laboratory at Hendon, an account of the opening of which was given on p. 944 of last week's issue of The Lancet, is as follows: Lord Atkin, Lord Dawson of Penn, Lord Trenchard; Sir Russell Scott, Permanent Under-Secretary of State, Home Office; Sir Edwin Deller, Principal of the University of London; Sir Bernard Spilsbury, Sir Frank Smith, Secretary, Department of Scientific and Industrial Research; Sir Robert Robertson, Government chemist, and Mr. Hugh Lett, F.R.C.S.

PROGNOSIS

A Series of Signed Articles contributed by invitation

XLIX.—PROGNOSIS OF MENTAL DEFICIENCY IN INFANTS

THE difficulties of making an accurate assessment of the mental prospects of young infants are almost in inverse proportion to age: that is to say, the younger the infant, the more difficult is it to make a correct prognosis. The usual mental tests applicable in the case of older children are inadmissible at a period of life—under one year of age—when there is practically no mentality on which to make observations. The prognosis is, however, rendered much easier when by reason of anatomical stigmata of degeneration, or by the presence of gross cranial malformations, the infant can be assigned to some particular pathological category, such as mongolism, cretinism, microcephaly, hydrocephaly, nævoid amentia, or amaurotic family idiocy, for in such cases the mental prospects have already been fairly well defined. The most difficult cases are those in which there are no external abnormalities to help us, or those in which there is some defect of one or other of the special senses, as in cerebral blindness or deafness, conditions which at least temporarily retard intellectual progress in all directions and make the prospects of future development appear more hopeless than they actually are. In such cases the greatest caution is required in giving opinions as to the probable course of mental evolution.

While it is obviously impossible for even the most experienced pædiatrician or alienist to estimate with accuracy the probable future mentality of a baby at a time when intelligence and will-power have scarcely begun to develop, certain principles of assessment may help us to avoid serious mistakes. These include: (1) A review of the family history. (2) An inquiry as to possible damage that may have been inflicted on the central nervous system by trauma or infection, and its extent. (3) Physical examination to discover evidences of congenital stigmata of degeneration, or malformations. (4) Examination for motor defects—paralyses, convulsions, incoördinations, and so forth. (5) An examination to discover defects in the special senses. (6) An examination for evidences of anomalies of nutrition.

FAMILY HISTORY

Although there is a tendency at the present day to belittle the factor of heredity in the ætiology of mental defect, none the less most alienists agree that in something like 80 per cent. of all cases of amentia of high or low degree there is some family history of psychoneurosis, mental instability, tuberculosis, syphilis, alcoholism, or consanguinity, either singly or in combination. The prognosis is adversely affected when more than one of these ætiological factors act in conjunction, but too much stress must not be laid on these factors; ultimately diagnosis must rest on the signs and symptoms of the individual child, and each case must be judged on its own merits.

DAMAGE TO THE CENTRAL NERVOUS SYSTEM

When secondary amentia is due to obstetric or other form of trauma, to cerebral hæmorrhage, to meningitis, or to encephalitis, the history of the case helps very greatly in the formulation of a correct prognosis. In these cases there is very rarely any external evidence of congenital stigmata of degeneration, while physical examination of the infant reveals as a rule nothing abnormal; in fact such infants usually appear far less mentally defective than they ultimately prove to be. Indeed, as the late Dr. J. Langdon-Down expressed it, the prognosis in cases of secondary amentia of the above kind "is contrary to what is often thought, inversely as the child is comely, fair to look upon, and winning." The prognosis in such cases must be judged partly by the degree of the estimated damage inflicted on the central nervous system, and partly by the character and rate of development of the motor and other functions, but as a rule there is no progressive deterioration of the mental state; the child remains in the same relative degree of backwardness with no improvement and no deterioration.

CONGENITAL ANATOMICAL STIGMATA OF DEGENERATION

In those cases in which mental defect in young infants is accompanied by such gross malformations of the cranial bones as those included in the list given at the beginning of this article, or by other anomalies of development and stigmata of degeneration, which enable us to give a name to the condition, it is possible to predict with some degree of accuracy the probable course of events. But quite apart from the more easily recognisable and clearly defined conditions included in these categories, some varieties of primary amentia are accompanied and distinguished by anomalies in the development of the skeletal system, as for instance of the jaws, the palate, or the digits, or of the soft parts such as the ears, the eyes, or external genitals, which assist the diagnosis of mental defect and adversely affect the prognosis. Anomalies of this kind are far too numerous to mention here in detail, but speaking quite generally it may be said that in any particular case the larger the number of such anomalies and the greater the degree of malformation, the worse is the prognosis of the future mental state.

In such gross defects as *anencephaly* and *cyclocephaly*, the prospects both as regards the mental state and the expectancy of life are almost hopeless, and not very much better in *oxycephaly*. In *microcephaly* and *hypertelorism* the child may survive early childhood, although it will rarely attain to a sufficient degree of intelligence as to be able to read and write or look after itself. The actual degree however will depend on the extent of the deformity—and run a more or less parallel course with it.

In *hydrocephalus* the prognosis depends on the type. In the non-communicating cases the prognosis is hopeless in spite of attempts at surgical treatment. In the communicating cases—i.e., the so-called external hydrocephalus—with early and appropriate treatment the prospects are comparatively good, unless nystagmus and optic atrophy have already supervened. I have myself had quite a number of patients who by continued dehydration treatment have eventually made good recoveries without any mental defect and without any ultimate deformity of the head. The final result however depends very largely on how far the hydrocephalic process has been allowed to progress before the treatment is commenced.

The treatment consists in limiting the intake of fluid, in the case of a baby under one year of age, to 16–20 oz. in the 24 hours, and in encouraging the output of water by diuresis, diaphoresis, and purgation. By these means it is quite easy to prevent any further increase in the dimensions of the head, especially if the ossification of the cranial bones is at the same time accelerated by the exhibition of vitamin D and lime salts; but such treatment cannot repair any damage already inflicted on the substance of the brain, nor can it cure the non-communicating cases.

The mental prognosis in *mongolism* varies very considerably, partly with the extent of the anatomical deformities, and partly with the degree of muscular atony and progress of physical development. In mild cases with persistent administration of thyroid gland and pituitary extract (anterior lobe), both physical and mental development may be very satisfactory and almost normal. I have myself had several patients who have grown up and earned their own living and who have ultimately presented very little outward evidence of mongolism. More than 50 per cent. of mongols remain imbecile; about 75 per cent. show moderate degrees of mental defect, and about 25 per cent. only slightly impaired intelligence. Their expectancy of life runs parallel with their mental development. More than 50 per cent. die before puberty, and quite a large proportion before they attain to adult age. It is a great mistake to believe that all mongols are imbecile, or even seriously mentally defective; slight degrees of mongolism have been known to run through whole families, in which only a few members could be classified as mentally defective.

In *cretinism* the prognosis is very good indeed if appropriate treatment is adopted at an early stage of the disease, but it must be continued up to adult age and in some cases, those in which there is complete absence of thyroid function, it must be pursued indefinitely. If the treatment is delayed till after the end of the first year of life there is likely to be some permanent mental defect, though physical development may be little impaired. If delayed to the end of the third year, the child, if it survives, is likely to be an imbecile.

The infantile form of *amaurotic family idiocy* is confined almost entirely to the Jewish race. It usually commences in an apparently normal infant between the third and sixth month, and there is progressive muscular debility, blindness, mental degeneracy, and increasing apathy to the surroundings. The capacity to suck and swallow is gradually lost and death usually occurs before the end of the first year, and before the child has learned to say simple words or acquire any recognisable intelligence. The prognosis in this form of the disease is quite hopeless, both as regards mental development and expectancy of life. In the juvenile form of the disease, which commences at the second year or later, the child may attain to some degree of intelligence and may live as long as five years, and have some slight degree of reason.

MOTOR DEFECTS

Since it is by action of some kind, that is to say by movement, gesture, or voice, that expression can be given to the emotions, thoughts, and other activities of mind, it is clear that in the final issue we must judge of the quality and potentiality for development of an infant's brain by action and conduct rather than by the external appearances of the skull.

The behaviour of young infants is not at first under voluntary control, nor dictated by intelligence. Their actions are purely reflex and instinctive, but all the same a considerable amount of light is thrown on the probable course of development of the mental faculties by the manner in which these purely reflex actions are executed, and the way they are modified by practice and experience. More will be said on this subject when we come to deal with the defects of the special senses. Incoördination of simple motor functions often affords the earliest indication of future mental defect.

Mentally defective infants at a very early age show clumsiness in the performance of the automatic motor functions, such as sucking, swallowing, defæcation, and micturition, and readily develop troublesome habits and mannerisms in respect to any or all of them. Athetotic, choreic, and rhythmical movements of the limbs, fingers, or eyes, if they occur during early infancy, are of bad prognostic significance, as also are tremors, twitchings, grimacing, sardonic smiling, and other facial contortions.

Spasticity is not a very common accompaniment of ordinary forms of primary amentia, but in cases of spastic diplegia or Little's disease, hypertonicity of the muscles may so interfere with the execution of voluntary or reflex movements that the child is often credited with degrees of mental defect which are not ultimately realised. In all cases of spasticity in young infants, uncomplicated by anatomical anomalies or other external stigmata of degeneration, great care should be exercised in giving an unfavourable prognosis of the degree of mental deficiency, but this does not imply that a favourable prognosis is always justified. Quite a considerable proportion of children suffering from spastic diplegia, without evidences of birth hæmorrhage and without epileptic fits, develop into very intelligent adults, but they practically never grow out of the physical infirmities due to the muscular spasticity, and remain permanent cripples, able perhaps to get about on crutches and use their arms for operations which do not require very accurate adjustment, but cripples all the same.

Convulsions, especially when frequently repeated and occurring on insignificant provocation, are of bad prognostic augury. According to Tredgold's figures, convulsions occur in 56 per cent. of idiots, 43 per cent. of imbeciles, and 11 per cent. of feeble-minded children. The earlier they occur, the more frequently they are repeated, the longer the attacks, the more severe the convulsions, and the less amenable to sedative and other forms of treatment, the worse the prognosis. Although no statistics are available to show what proportion of babies suffering from convulsions during the first year of life ultimately become perfectly normal individuals, my own experience is that if some genuine and temporary reflex cause, such as intestinal colic in early infancy, or teething at a later date, can be proved to be responsible for the convulsions, or if indeed a condition of spasmophilia due to a low blood calcium predisposes to the fits, the prospects of complete recovery and disappearance of the symptoms are extremely good in at least 75 per cent. of the cases.

A condition of paralysis, general muscular feebleness, or *hypotonia*, with delayed ability to hold up the head, to sit up, or to perform coördinated muscular movements is highly indicative of some fundamental defect in the child's nervous organisation, and suggests a bad prognosis from the point of view of the ultimate mentality, unless some serious condition of malnutrition or rickets is present to explain the symptoms.

DEFECTS OF SENSORY FUNCTIONS

Since all infants acquire a knowledge of their surroundings, and thereby develop in intelligence, through the medium of their sensory functions, it is clear that their degree of educability will depend largely on the acuity of these senses and on their opportunities for exercising them. A combination of deafness, blindness, and anæsthesia in infants must inevitably lead to total amentia, because infants so afflicted have no opportunities of coming into relationship with the outside world and thereby becoming educated through experience. In assessing, therefore, the mental prospects of an infant suspected of amentia, it is important to estimate the degree and extent to which these various avenues of education are open or closed.

In my capacity of medical adviser to the infants' department of the National Institute for the Blind, I have often to decide whether applicants for admission to its Sunshine Homes for blind babies are sufficiently normal to benefit by the education provided. As blind babies, unless specially educated, are always mentally backward as compared with normal babies, it is sometimes extremely difficult to assess the prognosis correctly, and it is very easy to take too pessimistic a view of the future. The same is also true of deaf infants. A useful criterion in such cases is to determine the amount of compensatory acuity acquired by the unimpaired senses. Blind infants who are otherwise normal always show a considerable degree of educability of the unaffected senses—i.e., those of touch and hearing—whereas those who are mentally defective show little or none. Blind babies who are also mentally afflicted generally take no interest in music, or in playing with toys and didactic material, whereas those who are normal take a great delight in gramophone records, and at a very early age will take their part in chorus singing and jazz bands, and in playing with Montessori and other kindergarten didactic materials and apparatus.

Although the actions of young babies are at first purely reflex and intuitive, and under little voluntary control, nevertheless, the youngest infant is provided with automatic mechanisms which enable it to inhibit painful and unprofitable reactions, and modify, improve, or stereotype those which afford pleasant or agreeable sensations. Thus it is to some extent possible to distinguish between normal and mentally defective infants by observing the nature of their reflexes and the way they modify them by experience.

Normal infants rapidly improve and perfect the common reflexes connected with a number of organic functions concerned with the use of the hands, the grasping of objects, with sucking, swallowing, defæcating, micturating, &c., whereas infants suffering from various degrees of amentia continue to repeat purposeless and often painful reactions. For instance, they will persistently bang their heads on the floor or against a wall over and over again, although in so doing they may experience considerable pain, or they will try to put their hands in the fire although they may have been punished over and over again for so doing. You cannot train aments to be clean, to eat and drink tidily, neither can you prevent them from trying to eat dirt, or from putting sharp, pointed, or rough objects in their mouths.

Idiots or low-grade imbeciles do not learn by experience, and cannot be trained or educated. Mentally defective infants often cry incontinently without reason or object. They suffer from persistent constipation, and on very slight provocation contract habits of vomiting. It is true that perfectly normal infants will acquire the same kind of habits if they are brought up badly, but they will not do so under good conditions of nursery management. Aments of every degree are difficult to train in good habits, and difficult to break of bad ones.

The ordinary mental tests such as the Binet-Simon or the Merrill-Palmer, which demand on the part of the examinee an understanding of the spoken word and are only intended to be employed in the case of children over three years of age, have no application in the testing of the mental state of infants under one year of age.

The degree and rate of educability of the nerve-cell, as also the capacity for improving or suppressing undesirable reflexes, are among the most useful of the prognostic factors. In normal infants, both the motor and the sensory functions, as well as the early gleams of intelligence, exfoliate in certain definite order, and at more or less definite age-periods. Infants ought to be able to grasp objects, fix their eyes and recognise persons or objects, hold up their heads, sit up, crawl, walk, smile, frown, and make intelligible utterances by certain specific dates. If an infant cannot recognise its own mother at six months, seize its bottle at seven months, sit up at eight months, stand at fourteen months, say "Mum-mum" and Dad-dad" at sixteen months, there is something radically wrong with its nervous organisation, and some degree of defect may be suspected; but too much reliance must not be imposed on the failure of any one single coördination to develop or improve, especially that of talking. It is when there is delay and abnormality in the performance of a number of the voluntary muscular coördinations that their true significance becomes revealed. Mental defect may be suspected and the prognosis estimated by the extent of the retardation with respect to the development of these functions.

NUTRITION

Some degree of nutritional anomaly generally accompanies the more serious varieties of amentia during the period of infancy. In spite of good feeding, mentally defective infants often fail to put on weight at a normal rate, or in spite of limitation of food sometimes grow inordinately fat. They also at times show great vulnerability of the skin to external trauma, suffer from trophic sores, and other instances of nutritional disturbances.

ERIC PRITCHARD, M.D., F.R.C.P.,
Medical Director, The Infants Hospital, London; Pædiatrician, Queen Charlotte's Maternity Hospital, London.

PSYCHOLOGICAL ASPECT OF SKIN DISEASE

ADDRESSING the Medical Society of Individual Psychology on April 11th, Dr. M. S. Thomson deprecated any tendency to assume that skin diseases are due to psychological factors, but gave examples of mental factors playing a part in their course. The most extreme perhaps is erythema pudicitiæ, an eruption which becomes manifest when a patient is stripped for examination before a person of the opposite sex. This is obviously nervous in origin. Dermatitis by artefact is very rare in compensation cases to-day and when error is made this is usually one of diagnosis; but artefact of the interest-demanding type is fairly common in young women and characterised by straight lines or angles, the patient's curious sidelong look, and the fact that a fresh site for the rash may quickly be found if comment is made on its absence.

Very occasionally, Dr. Thomson said, eczema results from strain—there is a classical case, associated with recurrent anxiety, recorded by Whitfield—but it almost always has well-recognised causes, though these may be detected only after exhaustive search. In lichen planus and psoriasis shock or overstrain is often a contributory factor; the former has been known to be resistant to all ordinary treatment and to disappear after a single lumbar puncture. Dermatitis herpetiformis was much more common during the strain of the war than now, and its course may vary directly with the degree of anxiety experienced by the patient: and the same may be true of rosacea. The capricious behaviour and sudden disappearance of infective warts may also be difficult to explain; nevertheless the causative virus has been isolated.

There are no psychogenic skin diseases, Dr. Thomson concluded, but there can be sensory neurosis of the skin either primary or grafted on to a pre-existing skin lesion.

BIRMINGHAM HOSPITALS CENTRE APPEAL.—Contributions to this appeal fund have reached a total of £740,276. The cost of collection has not exceeded 1 per cent.

INCREASED BODILY GROWTH OF SCHOOL-CHILDREN SINCE THE WAR*

By Georg Wolff, M.D.
FORMERLY SCHOOL MEDICAL OFFICER IN BERLIN

The extent of growth in man is primarily a function of innate constitution. It is an old observation that tall parents tend on the average to have tall children. Apart from this everyday observation—to which there are of course exceptions as in any biological variable—the close relation between the mean bodily dimensions of the parents and those of their adult children has been established by the correlation studies of Francis Galton,[1] founder of eugenics, and of his fellow worker and successor, Karl Pearson,[2] founder of modern biometry.

These results of biometry must in the *statistical* sense be regarded as definitely ascertained as well as thoroughly in accordance with individual experience. Undoubtedly we have also whole series of observations which suggest an environmental influence on the rate of growth, its pre- and post-natal velocity, if we may express growth as a function of time. Thus many investigations have shown differences between the heights and weights of children of the same ages in elementary schools and in secondary schools which might be interpreted as showing a superiority of growth of the children on the average better economically situated, to be an effect of social environment, feeding, care, and other environmental components. On the other hand, some persons look upon this not as the result of a steady environmental influence, but rather as the effect of selection inasmuch as children with both mental and bodily superiority tend to be sent to the secondary schools. Thus the problem can hardly be interpreted unambiguously. There is a conflict of opinion; no convincing proof can be deduced from either a biological study of inheritance or the study of environment in favour of one or other hypothesis.

The fact, however, of the superiority in growth of the children in the secondary schools is, as a matter of anthropometric statistics, unchallengeable. It is true that some years ago the Munich pædiatrist Pfaundler[3] in an elegant study of growth gave a wholly different interpretation. He sees in the shooting up of children in the better situated classes, not a superiority in growth over the children of the people but the precise contrary, inasmuch as he compares this rapid growth of the well-to-do children with the rapid, but unhealthy, growth of hot-house plants. But Pfaundler's comparison will hardly withstand criticism.

The scholars in the secondary schools, not only in height but also in weight, are superior to children in elementary schools of the same age. Oettinger[4] in a very careful study in Germany has dealt with this matter, and in the course of his work has taken the opportunity of criticising various popular index methods, among others the Livi and Rohr index, which is unsatisfactory on account of its inconstancy, since with the normal growth from year to year it must become smaller. If actual weight is related to the normal weight, as can only be done by taking into account the correlation of age, size, and weight, as has been done in America by Baldwin[5] and in a German-speaking country by Pirquet,[6] then secondary schoolboys show in their development a superiority, on the average, over children of the less well-to-do classes. Again, Rösle and Böning,[7] in their comparative study of school measurements in Jena for the year 1880, and again in 1921, found nothing to confirm Pfaundler's view of a pathological precipitancy in growth attaching to the pupils of secondary schools. They would rather see in a rapid springing up of height "a finely begun experiment sidetracked, when in comparison with the normal growth, in height, growth in other directions has suffered pathological changes." As a factor of the general improvement in bodily development they see the rise in the standard of living—"it is indifferent whether one is dealing with a whole population (as in 1921) or with a single school category (for example, the economically better placed children in the higher schools)." As a factor of unharmonious growth they are inclined to consider schools—the school, which as an enemy of the body frequently impedes the growth from being harmonious on both mental and bodily sides.

However important for the school medical officer may be support from the aspects of the physiology and pathology of growth, in order to enable him to make demands on the school (indeed out of school), I am of opinion that one should not exaggerate the influence of the school. And so I come to my own investigations, carried out over nine consecutive years, of young children on whom the influence of the school *has not yet begun*; *differences in the rate of growth* of considerable significance appear in different years. With these I shall compare school leavers who have been subjected to the school influence for at least eight years. Perhaps here the conclusions of exact anthropometry may have some light to throw upon the problem of inborn constitution and environment and the bodily development of the growing human being, particularly the school-child.

School Entrants

The anthropometric studies I am about to describe were carried out during the first six years as part of my school medical work, and in the last three upon the work of my successor in the same district of Berlin, using the same methods and material. The data relate to entrants in the years 1924–32, and to leavers who in the years 1925–33 were medically examined in connexion with choice of occupation. Those belonging to the first three entrance years, 1924–26, are derived from the birth years 1917–18 to 1919–20, that is to say, they were born in the worst period of privation of the German people; on the basis of eight years' schooling the leavers of 1932 belong to these birth years. The results bear the stamp of an individual statistical character; the collection of the original material, measurements, weighings, and their statistical elaboration were all controlled by one individual. The numbers in individual years are, however, as the computed errors of random sampling show, so large that some general conclusions as to the effect of under-nourishment on the growth of children cannot be rejected. Also there is evidence that this growth deficit is made up before puberty.†

The measurements were made in the spring of each calendar year, four to five weeks before the end of term (April 1st), or three months before leaving school

---

* A lecture delivered in the London School of Hygiene and Tropical Medicine (University of London) on March 1st, 1935.

† Precise methods of statistical anthropometric elaboration are described in detail in my monograph [8] to which the reader is referred for further demographic and medical details.

No. = number of (A) boys and (B) girls examined.

(Easter and Michaelmas). They were therefore made under approximately equal conditions, and the same measuring apparatus in the school medical officer's consulting-room was used by a specially experienced and controlled staff. Children clothed only in shirts were classified after measurement according to Martin's[9] nomenclature.

Berlin entrants only come to school at one time in the year, not as formerly at either Easter or Michaelmas. Consequently differences in the ages of school entrants to-day are larger than they used to be. They extend normally, without taking account of postponed entrants, over as much as fifteen months (at a usual age of entrants from 5½ to 6¾ years). A subdivision into half-yearly classes is necessary, and in the tables that follow I have divided entrants into the three age-group—5½–6, 6–6½, and 6½–7, as well as by sex.

In Tables I. and II. we have anthropometric results for 6265 entrants, namely, 3191 boys and 3074 girls, and in Table IV. for 4743 leavers, namely, 2448 boys and 2295 girls, subjected to school medical inspection during the period; that is to say, we have reasonably large numbers. Heights and weights of children are biological characters, the measurement of which, given an accurate apparatus and attentive use, is practically independent of subjective impressions.

It will be seen concordantly in boys and girls, year by year, that there is a distinct increase in the mean value of both height and weight. Particularly striking is the sharp difference between 1926 and 1927; here the increases in growth over a year amount to 2–3 cm. both in boys and girls in each of the three of the half-yearly classes, whereas since 1927 only a slight change appears. We have not therefore had a uniform increase from year to year, but rather a discontinuous process. This is of importance in the interpretation of the phenomenon of growth. The gross difference between the means of 1924 and 1932 ranges from 5·9 to 6·5 cm. in height and from 1·07 to 1·57 kg. in weight. A consideration of the standard errors of sampling shows that we have to deal with differences which, in the technical statistical sense, should be regarded as significant. The entrants are now taller than their predecessors. The increase of weight is equally striking. Errors of random sampling are computed in the next table for the differences in measurements between 1924 and 1932. (Table III.)

This shows that from 5½ to 6 years and 6 to 6½ years for both sexes the mean increase is more than three times its standard error, and is apparent in both age-groups. We have not quite so clear a case in the older entrants from

6½ to 7 years. This is of importance to the school medical officer and teacher from the practical point of view. From my measurements it appears that in every calendar year the older entrants from 6½ to 7 years show very little advantage, both in respect of height or weight; indeed, sometimes a disadvantage when compared with children six months younger. We seem to have in these older entrants the result of a sort of negative selection. Some of these children are children who were referred back by the school medical officer or were kept back by the parents in the previous year as being too weakly. The number of these is, of course, relatively small and the average measurements of these older entrants should not be regarded as normal values for their age class. Really they should be completed by the numbers of children of the same age who have already been a year at school.

In general, the impression derived from this analysis is that growth in the height of children is plainly influenced by environmental factors, particularly by the amount of nutrition provided before and after birth. We must not lose sight of the fact that the *births*, of the rather small entry in 1924 and 1925 and partly also of that of 1926, fell into the period of serious food shortage of the German people, namely, 1917–19. Children born then still showed six years later—school inspection years 1924–26—a distinct growth deficit, in my experience, in comparison with earlier and, still more, later born entrants. It is in the year 1927 that all three age-groups of both sexes first showed approximately stable values and we may say that we had reached from the phenotypic point of view a normal year, that is to say, one in which the structures capable of growth are no longer affected by the influences of a period of scarcity.

* Calculation of mean errors of differences from the formula: standard error of difference of means $= \sqrt{m^2_1 + m^2_2}$.

We have here, perhaps for the first time, an anthropometric study based on statistically adequate numbers of the after-effects of under-nutrition on growth in height and weight of the generation born in the hunger years of the war down to the close of early childhood. While the immediate effects of undernourishment on the human population were well enough known in the war years themselves, they were smoothed out in the first years after the war. Thus Schlesinger [10] reports that in school-children already in 1922–23 previous defects in weight were compensated by an abnormal increase in weight. Rösle and Böning even maintained that 1921 was, in their experience, a normal year, so that by then the war effects were almost compensated. This is, however, as we have seen above, not quite exact.

Our investigations of entrants relate to children born in the later years of the war. These children came into the world with body-weight less than normal, as Peller [11] has unambiguously demonstrated in the Viennese population, and suffered from this retarded growth still longer. These results of prenatal environmental influence, particularly the state of nutrition of the mother, on postnatal growth in height and weight are not without importance to the social hygienist, perhaps also in the biological study of inheritance. They confirm on mankind by means of the involuntary experiment of war-time nutrition what a student of heredity, Agnes Bluhm [12] had already found and statistically demonstrated in numerous animal experiments upon the retardation of growth in mice with low birth weights. In these large-scale researches, the simple correlation between weight at birth and body-weight at later ages was found. "Es treten dementsprechend reifere Früchte mit einem höheren Gewicht in das 'Kleinkindalter' ein als wenige reife," says Dr. Bluhm, of her generations of mice.

Our own studies of the variation in school entrants show that this may be generalised from animal experiments to the growing human beings. For our observations demonstrate with sufficient clearness that any deprivation of the mother due to emergency rationing does not pass without an unfavourable effect upon the height and weight of her children. Accordingly statistical deductive methods applied to the mass phenomena of human society are equal in value to experimental inductive methods provided changes receive their appropriate analysis. We reach for the human population the same conclusions as Bluhm derived from her experiments on animals, namely, that the intra-uterine rate of growth, while mainly determined by heritable influences, nevertheless is influenced by the environmental factor of nutrition and, above all, is subject to further postfœtal retardations; now studies of this can be followed to the end of early childhood. This dependance of growth in height and weight is parallel with the frequently observed retardation in school-children from economically unfavourable situated strata as compared with better placed children of the same age.

In the further course of these studies, which at first were confined to the years 1924–28, the economic world crisis developed with, particularly in Germany, increasing unemployment. Very soon in the press and in political and scientific circles the question was asked, "Has the economic world catastrophe made itself evident in the state of health of our people, as, for example, was the case in the war hunger years?" Were this so, it would be a question of the immediate effect of defective national nutrition. On this account

1933	123	153·6 ± 0·690 43·6 ± 0·724	98	155·5 ± 0·741 44·6 ± 0·792	135	154·2 ± 0·604 46·3 ± 0·654	98	155·4 ± 0·586 47·5 ± 0·739

anthropometric measurements on school entrants were continued; contrary to the expectations of many, as the figures in Tables I. and II. show, there was in fact no decline in the measurements of entrants in these years; on the contrary, there was even a small increase which, however, was well within the limits of random error. Further, the slight losses of weight in some half-yearly classes of the entrance years 1929 and 1932 are also, for the most part, within the reasonable bounds of chance fluctuation. At the most we may say that the average increase of weight does not quite keep pace with that of height, which is not in conflict with biological expectations, for the juvenile organism regularly lays down the building stones of the growth impulse, first in respect to length and only afterwards with respect to mass (see Schlesinger[10]).

On the whole we may say that the heights and weights of the entrants of a given age, since 1927, remained practically constant with a small upward tendency.

School Leavers

The results so far discussed relate to entrants in 1924–32; they must be completed by similar measurements on leavers obtained in the same administrative district in the years 1925–33. Medical examination, in connexion with the choice of a career, usually takes place three months before leaving, and the statistical anthropometric elaboration followed the general rules described above. It is, of course, of particular practical and scientific importance to learn something about the further bodily development during the years of schooling, at any rate at the beginning of puberty. Do the retardations in growth of the 1924–26 entrants persist or, in the course of the eight years of school life, which for the most part were of normal nutritional conditions, do we find a levelling out? *An exact comparison can only be given when the entrants in normal years become leavers.* However, the anthropometric results on leavers of the later years in comparison with earlier leaving years show a general improvement as will appear from Table IV.

From this Table, which sets out the averages and appropriate standard errors, we may draw the following conclusions. It appears again, as in the entrants, that a regular increase in height and weight has occurred in both half-year classes and for both sexes. In boys of the same age this increase in height in the course of the study amounts to 7–8 cm., in weight to, roughly, 5 kg.; in girls of the same age the increase in height is approximately 6 cm., in weight

TABLE V.—INCREASES IN HEIGHT AND WEIGHT OF SCHOOL LEAVERS FROM 1925–33
(Difference in cm. and kg. ± mean error*)

Difference ..	7·2 ± 0·889	4·7 ± 0·862	8·3 ± 0·906	5·5 ± 0·885
		GIRLS		
1933	154·2 ± 0·604	46·3 ± 0·654	155·4 ± 0·586	47·5 ± 0·739
1925	148·4 ± 0·626	42·6 ± 0·582	149·3 ± 0·631	43·5 ± 0·563
Difference ..	5·8 ± 0·870	3·7 ± 0·875	6·1 ± 0·861	4·0 ± 0·929

* Calculated from the formula: standard error of difference of means = $\sqrt{m_1^2 + m_2^2}$ (see Table III.).

approximately 4 kg. It should be remembered that girls in these age classes, as the Table shows, on account of the greater filling out of the figure associated with the earlier stages of puberty surpass boys in height and particularly in weight. It is only in the later stages of puberty that boys again take the lead in weight and height.

From the individual analysis year by year we may infer that, in contradistinction to the observations upon entrants, the increase has been a continuous one with deviations in particular years as one would expect from the statistical point of view. A sudden increase in all half-year classes for both sexes, as was noted among the entrants *between 1926 and 1927*, is not here observed; there is a greater increase perhaps for 14–14½-year-old boys between 1928 and 1929, but only in these, and this has no special significance since these individual values are subject to a high probable error. The range of variation, both in height and weight at the age of puberty, is somewhat wide, as is also therefore the standard deviation, when the number of leavers measured, particularly at ages from 14–14½ years, has become smaller in recent years for various reasons (decline in the birth-rate, changes in age of entrants, decrease in the school medical district). Consequently the standard error taken in the form $E_m = \frac{\sigma}{\sqrt{n}}$ has increased in recent years, and the range of these studies might profitably be extended by similar investigations in other countries and cities.

On the whole, however, the increases in height and weight which make themselves manifest in the period 1925–33 in the leavers must be regarded as significant; as a simple arithmetical calculation shows if one compares the beginning and ending values of the period of investigation and compares the differences with their standard errors as is done in Table V.

The considerable differences both in stature and weight lie beyond the ordinary limits of chance fluctuations, being in all four instances more than three times the standard error of the difference. Our children are, therefore, really bigger as appeared from the anthropometric investigation of entrants. A retardation in the bodily development of leavers in the years 1931, 1932, 1933, that is to say, those corresponding to the birth years from 1916–17 to 1918–19, does not appear when comparison is made with the previous years. There can, therefore, be no doubt in inferring that the growth retardation of war birth years, still manifest at the age of school entrants, has in the course of further growth, namely, in the period entering upon puberty, been compensated, always provided that no new dangers to nutrition occur. This is a positive and, in my opinion, important result of the investigation of leavers in a particular area; it makes it probable that among them as among entrants no new retardations of growth can be charged to the economic crisis.

Discussion

An increase in the rate of growth in the post-war time cannot be doubted. In this lecture it has been substantiated by means of systematic measurings and weighings of school entrants and school leavers year by year in Berlin, analysed by statistical methods. Within the nine-year period of investigation an increase in stature for entrants has amounted to from 6 to 6·5 cm., and for leavers, after eight years' schooling, to from 6 to 8 cm. on the average; the increase of weight in entrants has amounted to from 1·0 to 1·5 kg. on the average, in leavers it has amounted to from 4·0 to 5·5 kg. These increases are beyond the range of probable chance fluctuations. Our children are therefore really bigger.

The tendency to increase of growth in civilised men has long existed, as recruiting statistics for many countries and sporadic measurements of children in earlier times demonstrated. The cause of this increase in growth should be looked for in the general improvement of social and economic conditions, among these, of national nutrition. This improvement of nutritional conditions was first interrupted by the world war, particularly in Germany and Austria. That showed itself in the increase in mortality from tuberculosis, as well as in the decrease of bodily dimensions. After this famine crisis repair of the disturbance of growth both in children and in adults set in rapidly; restoration of bodily dimensions was, however, still interrupted by the after-effects of the war years of births. This was a late consequence of the scarcity. This is clearly seen in the investigation in the low measurements of school entrants from 1924–26, that is to say, years of birth 1917 to 1919–20; it also appears, however, that this retardation of growth did not persist for the school leavers. These older children born in the war years have made up their growth deficit. A permanent injury did not result.

These results of current measurements on school-children are of fundamental importance for the problem of the physiology of growth; they show, in fact, that the speed of growth in man, the tempo of which in the individual is determined primarily by inborn factors, may nevertheless be distinctly influenced by environmental factors, particularly the factor of nutrition from intra-uterine life to puberty. This dependence is parallel with differences in the growth of children in elementary and secondary schools, and these differences should be regarded as environmental rather than genotypic variations.

Connected herewith is the conclusion that the anthropometric method is of practical value in the judgment of individual cases, if standard tables, preferably prepared from a correlation of stature and weight and age, are available; but the method is also indispensable in the determination of population figures when comparative data from year to year are available. Here the school medical service has graver responsibilities than the pioneer worker, and has to work in defence of proper standards. Later on, the statistical elaboration of normal tables prepared from time to time, perhaps in connexion with the census enumerations, should be available and should prove an important instrument in the practice of demographic hygiene.

In stressing the environmental factors of growth I naturally do not mean to cast any reflection upon the great investigators, such men as Gregor Mendel, who, in the spirit of Newton's famous motto, *hypotheses non fingo*, have revealed, and will reveal the fundamental mechanisms of hereditary transmission. But I do venture to suggest that the facts I have described should give us some comfort in these days of depression when so much is heard of the degeneration of civilised peoples and of the danger of civilisation.

No doubt civilisation *is* in danger; it always has been in danger. Great emotional disturbances of the peoples of the world have always, for better or for worse, affected the material structure of human society. The apocalyptic horsemen—War, Hunger, and Pestilence—have ridden through Europe more than once; the generation now in being has seen them and will never forget the signs of their passage. But the hygienist, recalling the state of Europe in 1918–19, and comparing what then was with what now is, can encourage his colleagues in the field of statecraft, for progress in the field of public health—as illustrated by the figures I have given—is manifest. We may have the courage to repeat the words used by your great political philosopher, Edmund Burke, writing in a time of scarcity and depression, "Let us be saved from too much wisdom of our own, and we shall do tolerably well."

MEDICINE AND THE LAW

Inquests after Executions

WHEN a capital sentence is carried out in England the coroner must hold an inquest within 24 hours and the jury must inquire into and ascertain the identity of the body and whether judgment of death was duly executed upon the offender. At Wandsworth Prison on April 16th the coroner's jury which inquired into the death of Percy Charles Anderson (executed for the murder of Constance Drew-Bear of Brighton) demanded to see not only the body but also the scaffold. This excess of conscientiousness in the performance of the jurors' unattractive duties seems to have caused some difficulty for the governor of the prison who apparently stated that a special order from the Home Secretary would be necessary. There was some discussion about an adjournment for this purpose, but in the end the governor gave way while protesting against the creation of a precedent. The foreman of the jury cogently argued that in ordinary inquests the instrument causing death, such as a revolver or a razor, is produced; how could the jurors of their own knowledge properly declare the method of death unless they saw the instrument whereby Anderson's life was taken? The jury duly saw what it wanted and the usual verdict was returned.

The governor presumably relied upon some domestic order from the Home Office. The Capital Punishment Amendment Act of 1868 (which abolished public executions in cases of murder, though they are apparently still proper in cases of treason) authorises the Secretary of State to make rules and regulations "for the purpose as well of guarding against any abuse in such execution as also of giving greater solemnity to the same and of making known without the prison walls the fact that such execution is taking place." The present rules, made in 1902, briefly say that the mode of execution, and the ceremonial attending it, shall be the same as heretofore; a public notice of the date and hour appointed for the execution must be posted on the prison gate 12 hours before the execution and must remain until the inquest has been held; and the bell of the prison or of the neighbouring parish church must be tolled for 15 minutes after the execution. In all this there is nothing to exclude the coroner's jury from the scene of the hanging. "Jervis on Coroners" states that it is usual for the governor to let the jurors visit such parts of the prison as may help them to understand the case and to observe the prison routine. If so, the governor at Wandsworth seems to have been needlessly concerned over precedent. While capital punishment is retained, the Home Office may perhaps rewrite its rules; some fresh provision seems necessary to deal with the unedifying struggles between demonstrators and police now witnessed outside the prison walls.

Police Inquiries and Medical Secrecy

The chief constable of Hove has provided a fresh problem of professional secrecy. In his efforts to solve the mystery of what is known as the Brighton trunk crime Number 1, he inquired of all local medical practitioners whether any woman of the age and condition of the victim had sought advice and had subsequently failed to put in an appearance. The inquiry is natural and proper as a matter of routine in criminal investigation. If a diamond necklace disappears, the police would ordinarily circularise all jewellers and pawnbrokers. If a fragment of clothing is a possible clue to the identity of a body, outfitters, manufacturers, and laundresses would normally be expected to throw what light they could upon the mystery. So also the police may well feel it worth while to try the medical profession for a missing patient. The doctor, if aware that a patient has suddenly disappeared and that an unidentified body has been found, could hardly do less than coöperate. The duty of secrecy wears a different aspect if the patient is dead.

Do these considerations justify the police in insisting that the doctor shall furnish a list of his patients and a catalogue of their ailments? Of course not. Quite apart from any issue of professional etiquette, there is no legal compulsion to answer the interrogatories of the police unless there is some express statutory duty. The Official Secrets Act of 1920 is a case in point. There Parliament declared that failure to give information to the police on demand should be punishable as a misdemeanour. This provision, permanently reproducing a war-time regulation against spying, is one of the most arbitrary in the whole statute book. Its surprising inclusion among our peace-time laws is an eloquent indication that no such duty to answer a policeman's questions normally exists.

Medical practitioners may safely be left to decide for themselves how far they feel able to assist when appealed to as in the Brighton case. Some doctors feel impelled to guard professional confidences with special vigilance when it is the police who ask for information. Others incline to remember that doctors are also citizens and owe a duty to the community. It is a matter for individual consciences. It is by no means inconceivable that details disclosed by a doctor to the police about a patient believed to be dead might, through error or misunderstanding, give rise to a grievance (with a potential claim to damages) against the doctor on the part of a patient who in fact is still alive. If the State is going to ask a doctor to run these risks as a matter of course, does it propose to indemnify him against the possible consequences?

CHELSEA HOSPITAL FOR WOMEN.—At the annual meeting Lord Londonderry, the chairman, said that the hospital income would probably be some £1800 less than last year, and urgent requirements to be carried out would increase their commitments by £1500. The number of patients admitted had increased, but the enlargement of the east block had made it possible to reduce the waiting-list, while the paying floor was increasingly used.

VIENNA

(FROM OUR OWN CORRESPONDENT)

HAS INSULIN HELPED ?

Prof. W. Falta, addressing the Gesellschaft der Aerzte, has been giving his views on the expectation of life in diabetes. It is agreed, he said, that the disease is on the increase in all countries with a high western civilisation. The hopes aroused by the discovery of insulin have been fulfilled only in part. The experience of the last ten years has shown that mortality in the wealthier classes has fallen, so that the average diabetic lives longer; but among poorer people the effect is less obvious. In considering the value of insulin, however, one must discriminate between the various types of diabetes—notably the insulin-sensitive and the insulin-resistant. There are severe cases needing comparatively little insulin, and mild cases requiring a lot; diabetic children are mostly insulin-sensitive, but later in life they become resistant. Sensitiveness to insulin is associated with a "consumptive" type of disease, with ketosis and polyuria, whereas resistance goes with obesity, premature hypertension, and little tendency to ketosis. The first group, which are probably of purely insular origin, had formerly a poor prognosis; and here the use of insulin has altogether changed the outlook, so that even children will develop beautifully under its administration. In the non-insular (or rather extra-insular) cases dietetic measures play a more important part and more insulin is needed; the diabetes is constitutional in origin and complications are common. Nowadays, however, no patient in either group should lose his life in diabetic coma.

In summary, Falta's view is that despite the use of insulin the deaths from diabetes have increased. The reason, he holds, is that, thanks to the remedy, a larger number of diabetics are alive at the same time. Mortality has decreased in the earlier age-groups; in the later it has risen, because more patients live long. As the poorer classes are unable to maintain the necessary régime and diet they have a relatively high death-rate. On the other hand, hundreds of thousand of diabetics owe their life and capacity for work purely to the use of insulin.

CARCINOMA OF THE LARYNX

The Vienna Laryngological Society lately listened to a review by Prof. M. Hajek of the work on cancer of the larynx done during his directorship of the Vienna Laryngological Clinic from 1919–34. He reported on 393 cases operated on, and the trend of his paper was to show that provided radical extirpation is done the prognosis is not as bad as is supposed. In the early days there was great difficulty in getting the patients to consent to the mutilating radical operation. In the first few years after the war their general condition was so bad (dental caries, malnutrition) that laryngo-fissure was resorted to in many cases that might otherwise have had a more extensive operation; hence the indication for laryngo-fissure is not so strict in this series as in others published. Hajek also preferred this operation for patients over seventy on the ground that in old people the malignant process seems to be less progressive. Of the 79 patients treated by laryngo-fissure 44 per cent. lived for more than three years after operation, while 15 per cent. died within twenty days. Of those surviving more than three years 34 per cent. lived for more than ten years, and there was no recurrence in cases where the strict indications for laryngo-fissure could be kept. Total extirpation was done in 279 cases, of which 89 were classified as intrinsic cancer. Of these 19 per cent. died within twenty days, 32 per cent. lived up to three years (with 22 per cent. of recurrences), and 34 per cent. over three years (4 per cent. of recurrences). Of the 152 patients with extrinsic cancer 25 per cent. died within twenty days, 48 per cent. lived up to three years (with 38 per cent. of recurrences), and 17 per cent. over three years (only 1·5 per cent. of recurrences). It has to be borne in mind that extrinsic carcinoma of the larynx necessarily carries an exceedingly bad prognosis if left untreated. In all these cases the associated lymph glands were completely removed, and the figures show that secondary implication of the glands is not an absolute contra-indication to operation. In the 43 cases in which an incomplete operation only could be performed radiotherapy (radium or X rays) was always employed. Prof. Hajek's paper dealt only with surgical measures, but he offered the opinion that it is very useful to follow operation by irradiation. He is not yet prepared to give a definite verdict on the value of Coutard's method of X ray therapy, since it has not been long enough in use for an estimate of late results. As for surgery, he believes that operation is justifiable even in cases of doubtful prognosis, since it gives a fair chance of recovery, for a time at least.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

TEACHING OF NEUROLOGY

Prof. Edwin Bramwell retired from the chair of clinical medicine at Edinburgh University at the end of last year, but we are glad to know that he is to continue clinical teaching in neurology at the Royal Infirmary. Arrangements are to be made for him to deliver a clinical lecture every Saturday at midday, which will be open to any who attend the Infirmary teaching, and he will hold a neurological clinic in the medical out-patient department every Monday at 2 o'clock. This should be of great convenience to medical practitioners and members of the Infirmary staff, who will be able to refer cases to this clinic for Prof. Bramwell's opinion. It should also prove attractive to students and especially to post-graduates working in the hospital.

SPECIALISATION

Edinburgh teachers insist that their main duty is to teach the medical student to be a general practitioner, and they are critical of the over-development of specialisation. A disadvantage of the present arrangement, however, is that the cases of, say, heart disease are scattered throughout the various charges and are not readily accessible to those who wish to become expert in that subject. There is much to be said for the view that students should be taught by general physicians and even by general practitioners, but a certain amount of specialisation is obviously essential. It would be particularly gratifying if the Edinburgh school could develop specialisation to an efficient degree while at the same time preserving the present features of its clinical teaching. Prof. Bramwell's new clinic may inaugurate a happy solution of the problem. A little coöperation by members of the medical staff will enable a large proportion of the neurological staff entering the hospital to be seen in the neurological clinic. If the scheme proves popular, clinics for other specialties may develop in due course, without interfering with the general features of the hospital teaching.

On the surgical side the position is rather different. A medical specialist is of distinct value for the *diagnosis* of disease, since the treatment he advises can usually be carried out in the general ward. The surgical specialist, on the other hand, practises a method of treatment which he has perfected, and must therefore have beds at his disposal. To meet this necessity the surgical staff tend to favour the development of larger units within which specialties may be developed by the more junior members.

AUSTRALASIA

(FROM OUR OWN CORRESPONDENT)

A FACULTY OF MEDICINE IN BRISBANE

THE Queensland Government, in considering extension of the health services of the State, has appointed a committee to advise on the establishment of a faculty of medical science in the University of Queensland. There is already a faculty of dentistry.

A JUBILEE APPEAL

On April 5th both houses of the Commonwealth Parliament adopted an address of loyalty to the King to mark the twenty-fifth anniversary of his succession. At the same time the Government launched an appeal for the King George V. and Queen Mary Maternal and Infant Welfare Memorial Fund, to be established as Australia's commemoration of the Silver Jubilee. From its own revenue the Commonwealth Government will give £50,000, and contributions will also be made by the State governments. A special appeal has been made by the Governor-General, and the acting Prime Minister states that the Royal Australasian College of Surgeons, the British Medical Association, nurses' and women's organisations, and industrial associations are being invited to coöperate. The Government proposes that the money collected shall be spent by State agencies through existing channels and on a few main objects. One aim is to secure a measure of uniformity while reserving the general principle of local control. Attention will be paid to post-graduate courses for doctors, the instruction of medical students in obstetrics, the theoretical and practical training of midwives and nurses, the establishment of a self-contained maternity hospital unit, and better equipment and improvement of existing institutions, both in the country and in the city.

The rate of maternal mortality in Australia is higher now than it was in 1911, and it rose from 4·72 per 1000 live births in 1921 to 5·13 in 1933. Although the general death-rate has fallen and infantile mortality has steadily decreased, the death-rate of infants in the first week of life has remained almost stationary.

PANEL AND CONTRACT PRACTICE

Title to Medical Benefit

PRACTITIONERS are sometimes in doubt as to when a person newly insured becomes entitled to medical benefit. There is, of course, no waiting period for medical benefit as there is for sickness benefit; the fact of being insurably employed confers an immediate title to medical benefit. Some years ago a boy who was due to commence work for the first time on a Monday met with an accident on the previous Sunday and required treatment on the day on which but for his accident he would have commenced work. He had just left school and as he had not entered upon his duties no stamp had been affixed to a contribution card in respect of him, nor was one due. As, however, he was under a contract of service, the Minister of Health held that on the Monday he had become entitled to medical benefit and an insurance practitioner both claimed and received a fee in respect of a general anæsthetic administered for the setting of a fractured radius. Clause 7 (2) of the Terms of Service may be briefly paraphrased thus. If a person in applying for treatment represents that he is an insured person but cannot produce a medical card, the practitioner must give any necessary medical treatment; he may charge a fee by way of deposit, but in that event he must issue a receipt on the form G.P.4 provided by the committee for the purpose; he must issue a certificate if he would have been required to issue a certificate had the applicant been an insured person on his list; but he must not order drugs or appliances on an insurance prescription form until the applicant's title to benefit has been proved. In case of doubt it is wise to follow the procedure laid down in this clause. If the applicant is not entitled to benefit the doctor retains the fee. If he is entitled his name is added to the doctor's list as from the date on which treatment was provided and the deposit is refunded to the applicant and deducted from the practitioner's remuneration. If drugs are supplied by the practitioner he may, should the person be proved entitled to benefit, reclaim the cost from the insurance committee.

Leave of Absence

An insurance doctor recently applied for permission to be absent from his practice for a period of about twelve months in connexion with certain private business. Clause 11 (1) of the Terms of Service provides that all treatment shall be given by a practitioner personally, except where he is prevented by urgency of other professional duties, temporary absence from home, or other reasonable cause, and Clause 11 (2) lays it down that a practitioner shall not absent himself from his practice for more than one week without first informing the insurance committee of his proposed absence and of the person or persons responsible for conducting his insurance practice during such absence. Absence for twelve months could hardly be regarded as temporary absence from home, and the question to be decided is whether the cause given by the doctor for his proposed absence and for his non-fulfilment of the requirement as to personal service could be regarded as a reasonable cause. The practice falls within the area of three insurance committees and one of these committees has already decided in the negative.

Spinal Jackets

In July, 1934, regulations were made providing that, as from August 13th following, spinal jackets should be added to the list of appliances which may be prescribed for insured persons, when required for treatment of fractures, dislocations, or diseases of the spine. The Ministry of Health has now intimated that after consultation with the Insurance Acts Committee the list of drugs and appliances appended to the distribution scheme will be extended to include this appliance. As and when insurance committees amend their areal distribution scheme it will be possible for practitioners either to prescribe or to arrange for the supply of spinal jackets in the circumstances mentioned. In the latter event they will of course be entitled to recover the cost from the committee.

What is a Partnership ?

An insurance committee has approached the Ministry of Health with a view to determining whether the reference in the Terms of Service to a partnership refers to the whole of the practice or not. It appears that this question was considered years ago and that it was then held that the term "practice" in Clause 11 (8) must be construed to refer to the whole of the practice in respect of which the partnership exists. If the partnership exists only with respect to insurance practice the word would have to be construed accordingly.

PUBLIC HEALTH

Boarding-out of Mental Patients

THE twenty-first annual report of the General Board of Control for Scotland gives considerable space to the question of boarded-out patients. During last year 1249 pauper patients were thus cared for. The majority of these patients are defectives, and tribute is paid to the coöperation between the local medical officer, the public assistance officer, and the Board which enables the best conditions for the patient to be obtained. Numbers of patients are cared for on the outlying crofts, and guardianship has become in some cases almost a matter of heredity, the present guardians having been in contact with patients from their earliest days. In such instances the present guardians carry on a tradition of tolerance, patience, and skill which their grandparents first learnt. Very little objection is taken to the close mixing of normal children with defective adults, a mixing which in itself seems to arouse a sense of responsibility in the children. Licence has proved useful. The general consensus of opinion favours a short period of institutional care, but several examples are given of the process whereby children are transferred to guardianship after lengthy preparation of the parents for the step. The fact that the patient does in suitable instances return home from time to time undoubtedly helps. The defectives who do best are those who have had the advantage of training in special schools or at welfare centres before being boarded-out. The Commissioners stress the necessity of more accommodation of an institutional kind. A State institution is required for the specially difficult defective. Ascertainment is still far from perfect. The higher grade defective is not sufficiently marked out from the normal child at school. He goes out into the world, and only later comes under the notice of the authorities. In view of the considerable use made of guardianship in Scotland these cases might do well after they had been transferred to special schools. It is noted that two Commissioners of the English Board of Control have visited some of the boarded-out cases and were impressed by "the intelligence, culture, simplicity, and kindness" of the Scottish guardians. Surely such virtues are not peculiar to Northern Britain, but certain factors seem to work against a further extension of the practice. The high-grade defectives are an asset to mental hospitals in terms of work given; they help to bring down the cost per head. Boarding-out is a hazard. Many may feel that residence under hospital conditions is to be preferred. But when the strain placed upon hospital accommodation by serious psychotic cases is considered, and the durable results of the system in Scotland are remembered, it would seem that boarding-out is likely to prove a developing mode of treatment. Though little mention is made of the boarding-out of cases of chronic mental illness it is generally agreed that this mode of dealing with certain patients could be expanded. It is not only a matter of beds and accommodation. Nor is it only a case of giving more opportunities for guardianship to suitable people. Boarding-out is one of the main ways in which the public can recognise the common incidence of mental disorder and learn to overcome the repulsion which cuts across the progress of psychiatry and the humane treatment of the mentally afflicted.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 13TH, 1935

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 0; scarlet fever, 2430; diphtheria, 1211; enteric fever, 25; acute pneumonia (primary or influenzal), 1429; puerperal fever, 53; puerperal pyrexia, 134; cerebro-spinal fever, 23; acute poliomyelitis, 3; encephalitis lethargica, 6; dysentery, 22; ophthalmia neonatorum, 92. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 20th was 3590, which included: Scarlet fever, 1107; diphtheria, 1540; measles, 22; whooping-[illegible] ›ver, 18 mothers (plus 5 babies); [illegible]; poliomyelitis, 2. At St. Margaret's [illegible] ies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 20 (0) from measles, 8 (2) from scarlet fever, 28 (6) from whooping-cough, 45 (5) from diphtheria, 43 (9) from diarrhœa and enteritis under two years, and 180 (24) from influenza. The figures in parentheses are those for London itself.

The number of influenzal deaths still remains almost stationary, the reported deaths for the last few weeks (working backwards) being 180, 184, 181, 175, 145, 139, 83. This week these deaths were reported from 62 great towns, Manchester reporting 22, Blackburn 10, Portsmouth and Leeds each 7, Birmingham 6, Liverpool, Newcastle-on-Tyne, and Sheffield each 5, Bradford, Stoke-on-Trent, and Norwich each 4. (During the same week Glasgow reported 8 deaths, Edinburgh 7.) Edmonton and Enfield each had 1 death from enteric fever. Four deaths from measles occurred at Cardiff. Leeds, Liverpool, and Sheffield each reported 3 deaths from diphtheria, no other large town more than 2.

The number of stillbirths notified during the week was 251 (corresponding to a rate of 37 per 1000 total births), including 33 in London.

ROYAL WEST SUSSEX HOSPITAL.—At the annual meeting of the governors on April 11th Sir Osmond Brock, chairman of the finance committee, said that this hospital was trying to arrange with all the others in the district for a general appeal for a reduction in their rating assessment. The Bishop of Chichester, who presided, referred to the disappointing reply of the county council to a request for a grant of £6400 towards the provision of a maternity home. The area served by the hospital had seen steady building development and it was difficult to feel that the hospital should be expected, without assistance, to meet the needs of a population much larger than the one for which it was provided.

CORRESPONDENCE

SALT LOSS AS A COMMON CAUSE OF ILL-HEALTH IN HOT CLIMATES

To the Editor of THE LANCET

SIR,—In 1923 Moss[1] drew attention to the fact that miners, working at high temperatures and sweating profusely, often suffered from muscular cramps as a result of slaking their thirst with water. These cramps did not occur if they quenched their thirst with dilute solutions of saline fluid. This condition is also now known to occur in stokers working in ships under similar conditions of temperature.

I believe that loss of sodium chloride in the sweat is a frequent and often unrecognised cause of ill-health and loss of efficiency in the white inhabitants of tropical and sub-tropical countries during the hot seasons, owing to their continuous exposure to high temperatures, although conditions are less strenuous as regards exertion. During the months of May, June, and early July the average maximum daily shade temperature in the Punjab is in the neighbourhood of 110° F., the minimum rarely falling below 85° F.

Hunt[2] estimated the loss of fluid under unfavourable conditions during the hot weather in India at 30 pints per diem. As a result of 13 years' residence in the Punjab and North-West Frontier Province, I have come to the conclusion that the average amount lost by sweating during the hotter months of the year is in the neighbourhood of 12 pints under moderately favourable conditions and with light exercise, although very much larger amounts may be lost under conditions involving great exertion with exposure to sun. The proportion of sodium chloride—the main constituent of sweat—is estimated by some writers as high as 0·95 per cent., but Yas Kuno,[3] taking an average, estimates it at 0·3 per cent. Even admitting this low figure, the loss of sodium chloride from 12 pints of sweat would be some 16 grammes a day. In addition, the amount of chloride passed per diem in the urine of normal individuals is about 12 g.[4] The amount of chloride necessary for bodily metabolism is variously estimated by different writers, but the lowest estimate appears to be 4 g. per diem,[5] making a total requirement of 32 g. under the conditions normally found in the hot weather in warm climates. The amount of chloride taken in food and cooking probably does not usually exceed 15–20 g.[6] and is often much less, making a deficit of some 12–17 g. daily. Under unfavourable conditions of exposure and exertion or reduced salt intake it might amount to more than double this quantity.

The indigenous inhabitants of hot climates consider salt an extremely important article of diet and consume large quantities of it, whereas the white people merely regard it as a flavouring agent. It is no exaggeration to say that many Europeans, residing in the East, dread the onset of the really hot weather, because they never feel well while it continues. The least pronounced symptom complained of is [illegible] undue fatigue after moderate exertion, [illegible] common complaints in otherwise healthy people are apparently causeless lassitude, headache, [illegible] and inability to concentrate. I further believe that excessive sweating—in itself an unpleasant symptom of salt deficiency—may be followed as a major manifestation by heat prostration or exhaustion, and as a minor by prickly heat or muscular cramps.

During the last three hot weathers spent in the Punjab, by greatly increasing the intake of sodium chloride, I have very much diminished the [illegible] of the above disabilities in others and in myself. [illegible] usual method recommended of increasing [illegible] is to drink physiological saline solution [illegible] full strength (0·95 per cent.) or in various [illegible] down to quarter strength. The [illegible] are very unpleasant to many people [illegible] intelligent coöperation of the cook [illegible] to increase the amount of salt [illegible] may also be added at table, particularly [illegible] and gravy. The breakfast cereal [illegible] quantities of milk are consumed [illegible] able additional medium by which [illegible] may be increased.

I am confident that many [illegible] weather almost unbearable [illegible] so were greatly increased [illegible] to their daily diet. By [illegible] would largely prevent [illegible] disorders.—I am, Sir, yours [illegible]

London, April 23rd.

THE EFFECT OF [illegible] LACTIC ACID BA[illegible] IS[illegible]

To the Editor [illegible]

[1] On Acute Intestinal T[illegible]

should these gain access to milk. Pasteurisation thus robs the milk of the lactic bacteria—the all-important agents for the production of the necessary acid medium for the prevention of the growth of pathogenic micro-organisms. Hence, in investigations on the relative values of raw and pasteurised milk, it is essential carefully to consider the part played by the lactic bacteria in raw milk in the prevention of diseases caused by pathogenic micro-organisms; moreover, it is necessary to determine what practical risks are likely to ensue from the consumption of pasteurised milk in which the natural antiseptic agents —the lactic bacteria—have been destroyed.

(4) To what extent is the oxygen present in raw milk diminished by pasteurisation ? and what effect on general health, and, especially, the resistance against pathogenic micro-organisms, is likely to ensue from the consumption of pasteurised milk containing less oxygen than raw milk ?

Fresh unheated milk contains a considerable amount of oxygen, whereas stale milk and heated milk contain much less or none. Milk rich in oxygen has been found to have an important beneficial action on digestion; also it has been found by G. Arbour Stephens[2] beneficial in cases of anæmia, debility and insomnia. Since milk rich in oxygen has such a good effect on the blood in cases of anæmia, it is highly probable that fresh unheated milk of known good quality, and containing considerable oxygen, will be found to be a much more efficient agent than pasteurised milk deficient in oxygen for providing natural immunity against diseases in man and in animals.

This is one of the important points on which carefully planned researches are needed to obtain reliable information. As Sir Frederick Keeble,[3] Sir Arnold Wilson, Lord Iveagh and others have urged, it is only by thorough investigations on the many factors involved in the milk problem that we shall be able to gain practical and reliable knowledge about the relative values of raw and pasteurised milk.

I am, Sir, yours faithfully,

WALTER FEARIS,

Formerly Bacteriologist to the City of Cardiff and County of Glamorgan Public Health Laboratory.

Brightlingsea, April 17th.

SO-CALLED ACIDOSIS ATTACKS

To the Editor of THE LANCET

SIR,—I am glad that Dr. Paterson has brought into notice what he terms " so-called acidosis attacks." Though I could never claim that hardly a day passes when I did not see a case, working as I did with Dr. W. B. Cheadle and living for many years in touch with sick children, I have naturally seen many examples of the " old-fashioned " cyclical vomiting. Long before the days of the distinguished names mentioned in Dr. Paterson's paper the condition was thoroughly recognised, and I do not believe that those who had practical dealings with these cases ever seriously accepted acidosis as more than a fashionable label, representing a phase of scientific medical knowledge, recognising that such is usually more or less correct and usually perhaps the latter.

Cyclical vomiting was not a bad term. I have seen cases in which almost to the day attacks occurred every 4 or 3 or 6 weeks, and it is hardly to be supposed that an infection broke out at these regular intervals. On the contrary, observation and the results of treatment pointed to a gradual accumulation of what very old-fashioned doctors called "peccant matter" in the system. I have repeatedly seen those cyclical intervals gradually lengthen and finally disappear under medical treatment not directed to infection. The liver also has been long considered one factor at least in causation. In such cases the diet was controlled by the diminution—not the withdrawal—of fats and particularly of hot fats; some days before the suspected outbreak calomel or grey powder was given, the diet reduced, plenty of water advised, and magnesia, bicarbonate of soda with some rhubarb or bromide prescribed, and the attack averted or postponed. For me there is no better proof of the value of medical treatment than improvement in the health of the patient, and rightly or wrongly I have always thought this to be one of the objects of studying medicine.

Again I think whatever the theoretical views upon a medical problem may be, direct personal experience of improvement from a particular line of treatment is of value, though there are naturally the dangers of personal bias or obstinacy. It has long been common knowledge that these children are "highly strung," and I have seen a number of doctors' children who have been great sufferers from cyclical vomiting. The connexion between disturbances of the liver and of the nervous system is a most interesting one quite apart from infection, and cyclical vomiting during the intervals between attacks requires careful attention as the ancients well understood. It has always appeared to me that there is a relation between cyclical vomiting and the much more uncommon condition acholuric jaundice, but I know I shall be at once crushed by the sentence " increased fragility of the red cells."

I agree that infection is of importance in all hepatic disorders, but the object of this letter is to express my belief that many cases of so-called acidosis are not primarily due to infection, but to some metabolic disorder. I entirely support the desire for accurate diagnosis which has perhaps been made more difficult by abolishing the harmless imperfect term " cyclical" and the confusion caused by the term " acidosis."

I am, Sir, yours faithfully,

London, April 20th. F. JOHN POYNTON.

THE BIRTH OF APES

To the Editor of THE LANCET

SIR,—In a most interesting and illuminating paper read recently before the Royal Society of Medicine (see THE LANCET, March 23rd, p. 678) Mr. James Wyatt described the birth of a chimpanzee at the London Zoological Gardens. He inferred that it was born occiput first as in human birth, but the last stages were very rapid and this point may have been overlooked. As far as I have been able to ascertain the occipital method of birth would seem to be peculiar to man. If one looks at the shape of the skull in ape or monkey there is no occiput to speak of —they are born snout first like all animals, horses, cattle, dogs, rabbits, guinea-pigs whose forepaws are under the chin. I thought so when I was comparing the shape of skulls with shape of female pelvic brims at the Royal College of Surgeons some years ago (1929). I then made inquiries in India, where the monkey is sacred. An Indian doctor, who holds a chair at the Lahore Medical College, said to me, " Undoubtedly your view is right, the monkey *is* born face first." Prof. J. Jarcho, in his recent book on posture and practices during labour among primitive peoples, reproduces Hartman and Tinklepaugh's photographs of *Macacus rhesus* in labour taken at Baltimore (1929). Of 11 cases they photographed 6; in 3 cases where they mention presentation it was the face that emerged first.

---

[2] Heart and Spleen in Health and Disease, London, 1932.

[3] Milk Supplies in Relation to National Health, Nature, June 2nd, 1934, p. 809.

I suggest that it is the fact of occipital birth being peculiar to man that has invested that part of the human head with religious associations. All Eastern people regard the occiput of man as specially sacred. Among Hindus one lock of hair is carefully preserved in that region. After death, on the funeral pyre, that part of the head is broken to set the spirit free. Mohammedans always cover that part of the head, however small the cap, and in pictures of saints and angels, both Christian and Buddhist, we see the holy man depicted as having a circle of light round the sub-occipito bregmatic circumference of his skull. I therefore call it the halo measure for short. In the West we have the monk's tonsure, and the acolyte's cap just covering the occiput. In the maternity hospital Calvados, Normandy, where there were weekly baptisms, the infants were held in their swaddling clothes, face downwards over the font, and baptised on the occiput.

This distinction between the birth of man and the birth of the ape seems to me a fact worthy of more attention than it has yet received. In all animals the female pelvis is rounder than in the male. The pelvic brim is always the shape of the part of the animal to be born through it. Only civilised man violates this law.

I am, Sir, yours faithfully,

London, April 15th. KATHLEEN VAUGHAN.

ANÆSTHESIA FOR PAINFUL DRESSINGS

To the Editor of THE LANCET

SIR,—I recently spoke to a patient who had undergone an operation for excision of the rectum and she made mention of the severe pain she endured during post-operative dressings. It is apparent that many hospitals do not yet know of the value of Dr. R. J. Minnitt's gas-and-air technique for relieving the pain of this type of dressing. At the Wellhouse Hospital, Barnet, at the request of the late Lord Knutsford, we have carefully tested the value of the gas-and-air analgesia for use in the general surgical wards. We have found that for all types of painful dressings in both adults and children Dr. Minnitt's method gives excellent results. I feel that this should be more generally known as much suffering could be avoided.

I am, Sir, yours faithfully,

New Barnet, Herts, April 16th. JOHN ELAM.

HUGHLINGS JACKSON'S GENIUS

To the Editor of THE LANCET

SIR,—Most of the recently revived reminiscences of Hughlings Jackson have alluded to his great kindliness, generosity, modesty, wit and humour, enthusiasm for the truth, and those many other qualities which gave him the stamp of a perfect English gentleman; but, although we all recognise his outstanding genius, the recent centenary celebrations have not apparently stimulated the recital of any samples of that mastery of inductive logic which was so peculiarly his own. I feel therefore impelled to relate the following anecdote.

One day in his carriage with him, as we house physicians so often were, he told me of his observation that the knee-jerks were absent in lobar pneumonia. Then—after a pause: "You know, Stoddart, I think that the rabbit can have no lateral horns in its spinal cord." I looked interested but, knowing the old man so well, made no comment. He said: "In pneumonia there is an acceleration of respiration disproportionate to the pulse-rate—and rabbits are immune from pneumonia." I must confess that I felt sceptical; but Jackson asked W. S. Colman, then pathologist to the National Hospital, to cut sections of the spinal cord of a rabbit and, sure enough, the rabbit has no lateral horns. I wish Colman were still with us to tell the story. My point is that anybody can make such an observation by cutting sections and looking; nobody but Jackson could arrive at such a conclusion by discovering that the knee-jerks are absent in pneumonia.

I am, Sir, yours faithfully,

W. H. B. STODDART.

Cavendish-square, W., April 23rd.

A "CAUSE" OF EPILEPSY

To the Editor of THE LANCET

SIR,—In an annotation last week (p. 947) sulphur is mentioned as a new cause of epilepsy. The source of the sulphur was a hair lotion. Practical experience taught me, many years ago, that "hair restorer" and "sulphur hair lotion" might be innocent-looking names for lead hair dye. The essential ingredient, in at least one instance, was acetate of lead. That substance was not referred to, stress being laid upon the refined milk of sulphur. Lead encephalopathy is a rare and sometimes very puzzling condition. Epileptiform convulsions are common in diachylon poisoning . . . headache and vertigo are common in lead encephalopathy (Price: "Text-book of Medicine," 1930, p. 375). Then, among the exciting causes of epilepsy is acute intoxication by lead (Ibid., p. 1528). Typical epileptic convulsions in a severe case of lead encephalopathy, although puzzling at first, helped me considerably in the diagnosis.

A chemical analysis of the sulphur hair lotion would be useful.

I am, Sir, yours faithfully,

ALLAN EDWARD MAHOOD.

Haynford, Norfolk, April 21st.

PROGNOSIS IN PULMONARY TUBERCULOSIS

To the Editor of THE LANCET

SIR,—I should like to endorse what Dr. Vere Pearson, Dr. Warwick Preston, and Sir Pendrill Varrier-Jones have to say about the kind of occupation to which patients should return on completion of sanatorium treatment. Unfortunately the advice given them by well-meaning persons, including at times tuberculosis workers, is not always the best. Patients are frequently advised to seek work in the open air, often arduous and exposed to all weathers, rather than remain in an office or workshop. Open-air work is considered by many people to be of vital importance to the tuberculous person, whereas an occupation that is free from worry and provides a good wage is far more valuable. I expressed these views 25 years and more ago when I was in sanatorium practice, and repeated them in a report to the L.C.C. on the Employment of Tuberculous Patients (P. S. King and Son, 1928). One sentence in this report runs:

> "It cannot be too strongly emphasised that, with few exceptions, the best occupation for a tuberculous person is the one to which he is accustomed and at which he can earn a good income, provided it can be carried out under reasonably hygienic conditions."

American experts estimate that in their country 50 per cent. of all workers treated for tuberculosis

MEDICAL NEWS

Scottish Conjoint Board

As a result of recent examinations of the conjoint examining board of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow, the following candidates have been granted the diplomas of L.R.C.P. Edin., L.R.C.S. Edin., L.R.F.P. and S. Glasg. :—

K. R. Minto, H. A. Korn, H. S. Berent, Max Schmuschkowitz, G. G. Macrae, H. A. J. P. Strecker, L. J. W. Wurzburger, A. E. Martin, Hans Abrahamsohn, Kurt Strauss, R. K. A. van Someren, G. D. W. Adamson, Fritz Abrahamsohn, Anneliese Schloss, Alexander Buchan, H. D. B. North, Norbert Anderman, Balbina Lurje, Hugo Droller, T. A. B. Mason, G. P. A. A. Nayagam, Alexander Watt, Hartwig Buxbaum, Kurt Silverstein, William O'Callaghan, Alfred Model, Walter Misch, P. T. Weyl, C. V. De Biaso, Bruno Lux, Ernst Goldschmidt, Erwin Flatow, A. M. Geissa, Florizel Westbourne-Aird, E. St. M. Brett, J. C. MacDougall, H. A. Magnus, W. H. Jervis, Mohamed Ismail, Siegfried Simon, and Arthur Philipp.

University of Glasgow

On April 20th the following degrees were conferred :—

M.D.—W. R. Snodgrass (with honours); David Clyde (with high commendation); W. A. Murray, M. M. Scott, William Tennent, and J. A. Waterman (with commendation); John Leishman, E. W. McCormick, Jean M. Mackintosh, A. W. McRorie, C. D. F. Morton, and F. R. Wilson.

M.B. Ch.B.—A. M. Pugh, Theodore Crawford, and R. G. Henderson (with honours); D. H. Wallace, J. A. C. Knox, and J. B. Brown (with commendation); R. G. Anderson, S. Y. Baird, B. N. P. Bannatyne, R. S. Barclay, P. McI. Bennett, A. C. Blair, W. M. Boyd, Donald Campbell, Elizabeth N. Christie, D. S. Crawford, W. F. Cruickshank, I. McN. Drysdale, J. W. Eidlin, A. W. V. Eley, A. D. Fleming, Maev Gallagher, Mima M. Gemmell, W. R. Gemmell, H. B. Gillespie, Abraham Glasser, Julius Gordon, J. F. Harper, Phebe N. Harvey, Wolff Hirshow, Allen Iredale, A. C. Jacobsen, D. T. Kemp, A. S. Kitchin, P. H. C. Kodilinye. J. H. Levack, Louis Levine, Isidor Livingstone. James McAulay, John McCreadie, R. MacG. McGowan, A. F. McIntyre. J. P. McIntyre, G. N. MacKenzie, A. C. Mayer, K. R. Minto, N. R. Murdoch, A. M. Murray, Hugh Richmond, M. S. Robertson, William Sharpe, J. A. Sinclair, Solomon Slonimsky, J. A. Squair, Ralph Steinacre, Sarah Stewart, George Struthers, J. H. Taylor, Andrew Tracy, James Travers, E. H. Wallace, Jeanie F. Watson, I. B. L. Weir, David Wolfson, David Wright, and James Wyper.

Royal College of Surgeons of England

The lecture which was to have been given by Dr. W. B. Coley at the college on Wednesday, May 1st, has been postponed.

University of London

The Geoffrey Duveen travelling studentship in oto-rhino-laryngology will shortly be available and application is invited from graduates of the University. Particulars will be found in our advertisement columns.

University of Birmingham

The Walter Myers travelling studentship of the value of £300 is available for the year 1935–36, and is tenable at an approved university or hospital not in Great Britain or Ireland. Candidates must be under thirty years of age, and unless graduates of Birmingham must have worked at the Birmingham medical school for three years immediately preceding their application. Further information may be had from the dean of the medical faculty, The University, Edmund-street, Birmingham, 3.

University of Edinburgh

A lectureship in memory of the late Sir Edward Sharpey-Schafer has been founded, and will be administered by the University. Sir Charles Sherrington, F.R.S., has agreed to give the first lecture.

The sum of £15,000 has been given to the University by Mrs. Stewart Hall for the endowment of a lectureship in the pathology of the diseases of children.

Queen's University Club, London

The annual spring dinner of this club will be held at 7.30 for 8 P.M. on Thursday, May 2nd, at the Dorchester Hotel, Park-lane, London, W., with Dr. Thomas Carnwath, the president, in the chair. The hon. secretaries are Mr. R. Lindsay Rea and Mr. R. L. Dodds.

Royal Institution of Great Britain

On Friday, May 10th, Dr. C. S. Myers, F.R.S., principal of the National Institute of Industrial Psychology, will discuss the scientific approach to vocational guidance, and a demonstration of method as applied to an individual case will be given by Dr. Angus Macrae.

THE death of Sir Richard Rawdon Stawell, reported last week from Melbourne, is a tragic occurrence, for he was the president-elect of the British Medical Association and would have presided over the annual meeting to be held in Melbourne in September next.

Dr. John Innes Moir has been appointed a member of the Executive Council of the Colony of British Honduras. It was announced in THE LANCET recently that Dr. Moir has been appointed principal medical officer to the colony.

Demonstrations of Contraceptive Technique

On Thursday, May 2nd, at 2.30 P.M., a practical demonstration of the technique of the use of a variety of contraceptive methods will be given by Mrs. Marie Stopes, D.Sc., and Dr. Evelyn Fisher. Application for tickets (which will be supplied to medical practitioners and senior students only) should be made in writing to the hon. secretary, the Society for Constructive Birth Control, 108, Whitfield-street, London, W.1.

Indian Medical Service

The annual dinner will be held at the Trocadero Restaurant, London, on Wednesday, June 19th, at 7.15 P.M., when Major-General E. A. Walker, C.B., K.H.S., director of medical services in India, will preside. Officers can arrange to sit near their friends, as separate tables to seat eight will be provided. Tickets from the joint hon. secretary, Sir Thomas Carey Evans, Hammersmith Hospital, Ducane-road, London, W.12.

Institute of Child Psychology

A course of eight lectures on aspects of normal child life will be given at Friends House, Euston-road, London, N.W., on Wednesdays from June 5th to 26th. On each day there will be lectures at 6.15 and at 8.15 P.M. On the first day Dr. Margaret Lowenfeld will speak on play in childhood, and Dr. Hazel Chodak Gregory on the place of habit in development. During the course Dr. Lowenfeld will also lecture on play phantasy and experience; child's play and man's work; and comedy and tragedy in play. Other lecturers will include Dr. Alan Moncrieff (the effect of illness upon temperament) and Dr. Ethel Dukes (phases of development). Applications for tickets should be made to the lecture secretary of the Institute, 26, Warwick-avenue, W.9.

Two Deaths after HCN Fumigation

At an inquest held at Aldershot last week the coroner went very carefully into the circumstances attending the death of two children in a house which had been fumigated more than 24 hours previously with hydrocyanic acid gas. The fumigation of a group of four brick cottages was carried out on the Thursday by an experienced operator, who opened every door, window, and cupboard at 9.30 P.M., when he had finished, and he did not leave the house until 11.30 P.M., after testing the atmosphere and the bedding. There might, he said, have been some trace of gas in the house when he left, but he was satisfied there was no danger. On the following (Friday) morning, after the sanitary inspector had seen that all the doors and windows were wide open, the family was allowed to return. Four of the five occupants of the house were taken ill during the Friday night, when a girl of five was found dead in bed by her sister; the parents and a small boy were removed to hospital and recovered. Only one occupant of the house, an older boy, was unaffected. In an adjoining cottage a girl of 12 months was found unconscious, and died later. Dr. E. T. Ruston, who made the post-mortem examination, said that the baby girl had an excessive amount of lymphoid tissue which would make her more susceptible to cyanide poisoning. The jury returned a verdict of death from misadventure, adding a rider that "in future, owing to the extremely dangerous nature of the gas, more competent supervision should be given by those responsible, and also two men should be employed, and the final certificate for re-entry into the house fumigated should be given by the medical officer of health."

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

The following officers qualified at the examination for the rank of surgeon commander held recently: Surg. Lt.-Comdrs. A. A. Pomfret, E. C. Davies, R. G. Anthony, E. J. K. Weeks, C. Keating, E. B. Pollard, J. C. Souter, J. Cussen, and D. C. Drake. Surg. Lt.-Comdrs. Pomfret, Pollard, and Souter qualified for accelerated promotion.

Surg. Comdr. (D.) J. R. Palmer placed on the Retd. List at own request, with rank of Surg. Capt. (D.).

Surg. Lt.-Comdr. (D.) A. Lawrey, O.B.E., is promoted to rank of Surg. Comdr. (D.), and Surg. Lt. H. L. Belcher to rank of Surg. Lt.-Comdr.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. W. G. MacLean to *Valiant*.

Proby. Surg. Sub-Lts. P. S. Luffman to *Drake* for R.N. Hosp., Plymouth, and P. de Bec Turtle to *Valiant*.

ROYAL AIR FORCE

Flying Offrs. R. G. James and J. W. Patrick, both to R.A.F. Depôt, Uxbridge.

The following short-service and non-permanent officers have been notified that they become due on the dates stated for transfer to the Reserve on completing their period of service on the active list:—

Dental Branch.—Flight Lts. S. C. Allen (Oct. 13th); F. F. Kennedy (Oct. 15th); and C. R. Stone (Oct. 31st). The officers have been asked whether they desire to be considered for an extension of service to ten years on the active list (five years for Flight Lt. Stone).

Permanent Commissions.—The Air Council have decided on the procedure to be adopted in connexion with the appointment of officers to permanent commissions in the medical branch. Under the revised constitution of this branch, published last May, all officers are entered in the first instance for short service.

The grant of permanent commissions will be by selection, an average of six vacancies being offered each year. Selections will be made twice yearly, in May and November, and the normal zone for consideration will be during an officer's second year of service. In this way the qualifications of each officer will be balanced against those of his contemporaries so as to secure a strictly equitable consideration of the merits of all competitors.

After consultation with their principal medical officers A.Os.C. will furnish to the Air Ministry by May 15th and Nov. 15th each year a report on all eligible medical officers holding short-service commissions, stating in each case whether or not the officers are recommended as suitable for selection. Recommendations are to be arranged in order of merit. Although the normal zone will be between one and two years, reports will continue to be rendered until the officers have completed the three years' active list period of their commissions.

DEATHS IN THE SERVICES

The death occurred on Easter Sunday, April 21st, of Major Robert Hemphill, D.S.O., R.A.M.C., medical officer at the Royal Military Academy, Woolwich, who lost his life by falling from a cliff at Kellan Head, Cornwall, while photographing a buzzard's nest. He was the eldest son of the late Canon Hemphill of Belfast. Born in 1888, he was educated at Trinity College, Dublin, graduating in 1912 and at once joining the R.A.M.C. He served in the European war as a temporary lieut.-colonel, was mentioned in dispatches, and was created D.S.O. in 1918. In 1929 he was posted staff surgeon at Cairo. At school and college he was a keen Rugby football player, was in his university team from 1908 until 1912, and in the latter year received international caps for Ireland against England, Scotland, Wales, and France. In 1913 he played for the Army. While in Egypt he represented his corps at lawn tennis, cricket, and golf. He was a member of the R.A.M.C. team that won the Inter-Unit Golf Championship in 1930–31. Major Hemphill married in 1915 Kathleen, daughter of the late Mr. and Mrs. H. Augustus Smith of Bitterne, Hampshire. His wife lost her life in an attempt to rescue her husband after his fall, and their son nearly shared their fate in a gallant attempt at rescue.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, April 30th.

Therapeutics and Pharmacology. 5 P.M. Dr. C. A. Neymann (Chicago): The Treatment of Disease by Means of Electro-pyrexia.

Pathology. 8.30 P.M. Dr. Claus Jensen (Copenhagen): The 1934 Epidemic of Poliomyelitis in Denmark. Other speakers: Dr. G. H. Eagles, Dr. H. S. Banks, Dr. E. W. N. Hobhouse, and Dr. J. D. Rolleston.

Wednesday, May 1st.

History of Medicine. 5 P.M. Annual General Meeting. Dr. A. P. Cawadias: The Medical Art of Maimonides and its Influence in the Development of Medicine. Dr. W. M. Feldman: Maimonides: His Life and Work.

Surgery. 5.30 P.M. Annual General Meeting.

Friday.—3.30 P.M. (Queen's Hospital), Dr. A. V. Neale: Demonstration of Medical Cases.

ROYAL INFIRMARY, Dundee.

Thursday, May 2nd.—3.15 P.M., Mr. Moodie and Dr. Scott: Clinical Eye Cases. 4.15 P.M., Dr. F. M. Milne: Arterio-sclerosis and its Treatment.

GLASGOW POST-GRADUATE ASSOCIATION.

Wednesday, May 1st.—4.15 P.M. (Royal Infirmary), Mr. Donald Duff: Surgical Cases.

Appointments

Brinton, D., B.M. Oxon., M.R.C.P. Lond., has been appointed Assistant Physician to the National Hospital, Queen-square, London.

Fickling, B. W., M.R.C.S., L.D.S. R.C.S. Eng., Assistant Dental Surgeon to St. George's Hospital, London.

Fickling, E. L., M.R.C.S., L.D.S. R.C.S. Eng., Dental Surgeon to St. George's Hospital, London.

Harris, B. P., M.B. Camb., Assistant Resident Medical Officer to Queen Charlotte's Maternity Hospital.

Jackson, H., F.R.C.S. Eng., Assistant Surgeon to the National Hospital, Queen-square, London.

Jones, **Evan**, M.B., M.R.C.P. Lond., Resident Medical Officer to the National Hospital for Diseases of the Heart, London.

MacVicar, W., M.D. Manitoba, F.R.C.S. Edin., Medical Officer to the Christie Hospital and Holt Radium Institute, Manchester.

Morgan, B., M.R.C.S. Eng., Assistant Pathologist to the Royal Infirmary, Sunderland.

Nankivell, J. W., M.B. Lond., F.R.C.S. Edin., Hon. Assistant Obstetric Surgeon to the Royal Victoria and West Hants Hospital, Bournemouth.

Nolan, G. **Russell**, M.B. Sydney, D.M.R.E. Camb., Assistant Radiological Officer (locum) to the Christie Hospital and Holt Radium Institute, Manchester.

Osborne, J. W., M.D., B.S., Out-patient Medical Officer to the National Hospital for Diseases of the Heart, London.

Hospital for Consumption, Brompton.—The following appointments are announced:—

Brooks, W. D. W., B.M. Oxon., M.R.C.P. Lond., Medical Registrar;

Lander, F. P. L., M.D., M.R.C.P. Lond., Medical Registrar;

Fitts, C. H., M.D. Melb., M.R.C.P. Lond., Resident Medical Officer;

Gowar, F. J. S., M.B. Lond., F.R.C.S. Eng., Resident Surgical Officer; and

Glick, L., M.B. Leeds, Assistant Resident Medical Officer.

Certifying Surgeons under the Factory and Workshop Acts: Dr. L. E. A. B. **Farr** (Andover, Hampshire), and Dr. J. N. M. **Fairley** (Dunblane, Perthshire).

Medical Referee under the Workmen's Compensation Act, 1925: Dr. H. G. **Garland**, of Leeds, an additional Medical Referee for the Dewsbury and Leeds County Court Districts (Circuit No. 14).

Vacancies

For further information refer to the advertisement columns

Accrington, Victoria Hospital.—H.S. £150.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.

Banbury, Horton General Hospital.—Res. M.O. At rate of £150.

Barnsley, Beckett Hospital and Dispensary.—Res. Surg. O. £300.

Bath, Royal United Hospital.—Out-Patient and Cas. O. At rate of £150.

Bedford County Hospital.—First and Second H.S. At rate of £155 and £150 respectively.

Birmingham, Dudley-road Hospital.—Jun. M.O. At rate of £200.

Birmingham University.—Walter Myers Travelling Studentship. £300.

Bradford Royal Infirmary.—Two H.S.'s. Each at rate of £135.

Bridgend, Glamorgan, County Mental Hospital.—Laboratory Research Asst. £350.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. and H.P. Each £120.

Brighton Sanatorium and Infectious Disease Hospital.—Jun. Res. M.O. At rate of £250.

Bristol General Hospital.—Sen. Res. M.O. £200.

British Medical Association, Tavistock-square, W.C.—Asst. Med. Secy. £800.

Burton-on-Trent, General Infirmary.—Cas. O. and H.P. £150.

Cambridge, Addenbrooke's Hospital.—Two H.P.'s. Each at rate of £130.

Charing Cross Hospital, W.C.—Hon. Anæsthetist.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall.—H.P. At rate of £150.

Coventry and Warwickshire Hospital.—H.S. for Aural and Ophth. Depts. At rate of £125.

Denbigh, North Wales Sanatorium.—Asst. Res. M.O. £200.

Dundee University College.—Chair of Physiology.

Eastbourne, Princess Alice Memorial Hospital.—Res. H.S. £150.

Eastbourne, Royal Eye Hospital, Pevensey-road.—H.S. £100.

Edinburgh Royal Infirmary.—Superintendent. £800.

Evelina Hospital for Sick Children, Southwark, S.E.—H.S. At rate of £120.

Winchester, Royal Hampshire County Hospital.—H.S. At rate of £125.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £150.

Worksop, Victoria Hospital.—Two Residents. At rate of £150 and £120 respectively.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Ellon, Aberdeenshire; Aberlour, Banffshire; Bewdley, Worcestershire; Brentwood, Essex; St. Clears, Carmarthenshire; Anstey, Leicestershire; Towcester, Northamptonshire; and Blairgowrie, Perthshire.

Births, Marriages, and Deaths

BIRTHS

Denning.—On April 17th, at Clifton, the wife of Lieut. Gordon Denning, M.R.C.S. Eng., R.A.M.C., of a son.

Gibbens.—On April 17th, the wife of Gerald Gibbens, M.B. Lond., of Sidmouth, Devon, of a son.

Giles.—On April 17th, at Colwall, Malvern, the wife of O. Pemberton Giles, M.B. Birm., of a daughter.

Gooding.—On April 18th, 1935, at "Dhoonglen," Ditton-road, Surbiton, Surrey, to Margaret (née Protheroe), wife of Stanley Gooding, M.D.—a daughter.

DEATHS

Bassano.—On April 21st, at Lindfield, Sussex, Thomas Matthias Bassano, M.B. Edin., late of Colchester, Essex, in his 68th year.

Black.—On April 13th, at Rotherfield, Sussex, James Black, M.B. Camb., F.R.C.S. Eng., late Lecturer on Anatomy, Westminster Hospital, aged 82.

Gay.—On April 20th, John Gay, M.D. Durh., D.P.H. Eng., of Upper Richmond-road, S.W.

Hemphill.—On April 21st, accidentally killed, with his wife, at Trebetherick, Cornwall, Major Robert Hemphill, D.S.O., M.B. Dub., R.A.M.C.

Norman.—On April 14th, at Oakham, Alfred Blake Norman, M.R.C.S. Eng., L.R.C.P. Edin., aged 85.

Troup.—On April 14th, at Southport, James Troup, M.B. Aberd., late of Whitefield, in his 69th year.

Utley.—On April 1st, at Suva, Fiji, B. Temple Utley, M.R.C.S. Eng., aged 39.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

A POCKET INSULIN CASE

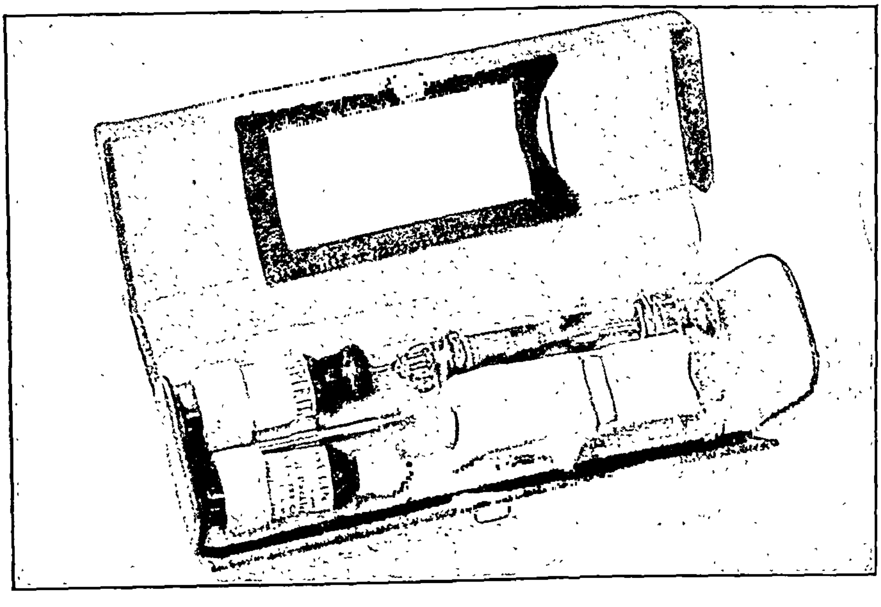
WE have received from Dr. E. E. Claxton, of Folkestone, the following description of a case which he has designed to contain all the requirements for insulin injections. It is to be carried in the pocket or handbag and is always ready for immediate use. The syringe is held by a clip, and the point of the needle is protected by and held inside a rubber-capped spirit bottle. Bottles containing spirit and insulin are mounted in flexible loops and allow access without removal from the case. There is also a pocket for cotton-wool and a clip for a spare needle. Provision is made for a tablet of glucose or a lump of sugar.

The case, which is of leather, is light and handy and made for hard wear. The inside, being lined by waterproof material, is sterilisable by wiping with a swab of cotton-wool soaked in spirit. The spirit bottle can be refilled by the owner either by removing its rubber cap and replacing it or by filling the syringe with spirit and squirting it into the bottle through the rubber cap. When the cap becomes worn and punctured the bottle can be exchanged for an old insulin bottle which answers the purpose satisfactorily.

Method of use.—Spirit is drawn into the syringe without removing the latter from the case. Having done this, the syringe is removed and spirit squirted on to a small piece of cotton-wool which is used for sterilising the cap of the insulin bottle and also for preparing the skin for the injection. The syringe is now charged with insulin in the usual manner and this can be done without removing the insulin bottle from the case. The injection is given and the needle reinserted into the spirit bottle through the rubber cap, which effectively holds it in position. The syringe is then pressed home into its clip. Having drawn some spirit out of the spirit container, the slight negative pressure thus produced prevents any leakage.

Advantages of the case.—It is very small, goes easily into the pocket or handbag, and contains everything necessary for injection. The only article to be removed from the case for the purpose of injection is the syringe. The inconvenience of arranging bottles, cotton-wool, and so on on a table or shelf when giving the injection is thus avoided. It is impossible to drop the insulin bottle as it is not removed from the case.

The case takes a standard record insulin syringe and is made to hold any make of insulin. It can be obtained empty or fitted up from Messrs. John Bell and Croyden, Messrs. Allen and Hanburys Ltd., Messrs. S. Maw Son and Sons, Ltd., and Messrs. C. L. Bencard Ltd.



PSYCHOLOGY IN THE HOME

SOME parents are profoundly interested not only in the minds of children but also in ascertaining the part they themselves play in the making and marring of these immature minds. Dr. F. H. Dodd[1] has attempted to help them in this self-imposed task; his exposition is sober and sound; though he does not indulge in any recondite analysis of the child mind, what he does give us is fair and beyond criticism. He might with profit have dealt more adequately with his subject had he considered many of the unconscious motives governing child behaviour. But it must be remembered that this book is primarily designed for laymen, and he might well have befogged the issue had he dealt with more than the manifest content of family life and the children in it.

SPUMAN FOAM THERAPY.—We have received from Medical Laboratories Ltd., 40, Pall Mall, London, S.W.1, samples of four preparations put on the market by Luitpold-Werk, Munich, through their agency. The preparations are entitled lactic acid Spuman, salicylic acid Spuman, Spuman with a 2 per cent. addition of sulphate of zinc, and Tampospuman. All these are directed to the treatment of inflammatory conditions of the female genito-urinary tract. Spuman contains bismuth and thymol made up with potassium boricotartrate, and can be combined with tannic acid, with ichthyol, with nitrate of silver, or with sulphate of zinc and other salts in accordance with the particular treatment required. The various preparations are supplied in a small flat cone, to which the word "stylus" is given, and on insertion of the stylus into the vagina and cervix a colloidal mass of foam is formed, which interpenetrates the surface of the mucous membrane and its folds. The recommendation for vaginal application in adults is one stylus of 1 g.; for urethral application or for children half a stylus is said to produce the desired effect, but the dosage and direction of treatment vary with the obstinacy of the case. The medical evidence submitted is from various German clinics and is of favourable character.

ERRATUM.—The experimental histological studies of lymphatic capillaries by B. D. Pullinger and H. W. Florey, which was the subject of editorial comment in THE LANCET last week, was published in the *British Journal of Experimental Pathology*, 1935, xvi., 49. The reference was omitted by a printer's error in some of the copies of THE LANCET.

NEW ASPECTS OF DEFICIENCIES IN NUTRITION*

By Donald Hunter, M.D., F.R.C.P. Lond.

PHYSICIAN, WITH CHARGE OF OUT-PATIENTS, TO THE LONDON HOSPITAL

In the last 25 years the progress of our knowledge of nutrition has been comparable to that of bacteriology at the end of the last century. Following early clinical observations suggesting a relationship between diet and disease the experimental method came into extensive use for investigating the influence of diet upon the growth and well-being of animals. Vitamins were identified and rapid progress has culminated in the recent synthesis of ascorbic acid, the first complete victory of chemists in the field of nutrition. Studies have concerned not only the vitamins but also the metabolism of iron, calcium, phosphorus, and iodine. And now an entirely new method of approach to problems of nutrition has been opened up by the Harvard workers in their studies of pernicious anæmia. Their discovery of a conditioned dietary deficiency disease may well prove to be a more important conception in nutrition than anything which has gone before.

Rickets and Osteomalacia

Pathologists, chemists, and clinical workers are agreed as to the essential identity of rickets and osteomalacia. What difference exists is merely that of age-incidence: osteomalacia is adult rickets. In the industrial towns of England to-day rickets is still a common disease. Osteomalacia is endemic over wide areas in Northern India, Japan, and Northern China, and occurs sporadically in certain parts of Europe. So far as England is concerned, osteomalacia does indeed exist in the distressed areas of the Midlands and the North, but fortunately it is still rare.

Morbid anatomists agree that in rickets and osteomalacia the essential abnormality is a deficient calcification of osteoid tissue. This deficiency is generalised throughout the skeleton. Pommer (1885) considered that in both diseases the broad osteoid seams were due to deficiency in the calcifying mechanism which should convert osteoid tissue into true bone. The experimental studies of E. Mellanby (1918, 1919) constitute the discovery of the cause of rickets. He produced the disease in puppies by deficient diets and cured it by the use of fats containing the antirachitic vitamin. Meanwhile the antirachitic power of ultra-violet irradiation was discovered by Huldschinsky (1919). In children suffering from severe rickets he demonstrated by radiograms the healing effects of the mercury vapour quartz lamp and of sunlight. In 1924 it was discovered that certain foods developed antirachitic powers when exposed to ultra-violet irradiation (Hess and Weinstock). It has since been possible to cure rickets in children by feeding them on irradiated foods. It is the sterols in such foods that can take on antirachitic potency, in particular ergosterol, for vitamin D is a derivative of this substance (Rosenheim and Webster, 1927). In the case of the skin the antirachitic action of ultra-violet irradiation is probably due to the synthesis of vitamin D from the ergosterol which it contains. In 1930 Webster and his co-workers isolated vitamin D in pure form. They extracted ergosterol from yeast and irradiated it in alcoholic solution as it passed through quartz tubes. They then purified the irradiated ergosterol.

The pure vitamin is called calciferol from its power to induce calcification in tissues, especially in osteoid tissue. It is 300,000 times as potent as cod-liver oil weight for weight. The daily requirement for health has been estimated as 0·075 mg. Its physical and chemical properties are quite well worked out and it can justly claim to be the first vitamin standardised on a chemical and physico-chemical basis. The isomeric change responsible for the conversion of ergosterol to calciferol is at present only a matter for speculation; the synthesis of either substance presents problems of extreme technical difficulty.

The blood chemistry is comparable in experimental rickets of rats (McCollum, 1921), in children with rickets (Howland and Kramer, 1921), and in women with osteomalacia (Miles and Feng, 1925). The plasma phosphorus and sometimes the serum calcium is diminished. Adequate treatment restores the low figure to normal. In the absence of vitamin D the utilisation of calcium and phosphorus is impaired. The low blood phosphorus or calcium is promptly restored to normal by the use of cod-liver oil, calciferol, or ultra-violet irradiation. At the same time ossification begins to proceed normally.

Unfortunately those foods that contain generous supplies of calcium or vitamin D are either not generally popular or are rather expensive. They include milk, butter, cream, sardines, sprats, herrings, and green vegetables. It is certain that the majority of people living in towns run the risk of getting insufficient supplies of vitamin D. Except for pregnant and lactating women, adults probably do not need much, but not so the children. Cod-liver oil should be given daily throughout the winter months to children, in whatever social class; during the summer the skin should be slowly browned by exposure to the sun. E. Mellanby (1922) has proved that cereals are rickets-producing, partly because they contain an anticalcifying substance which interferes with calcium and phosphorus relations, and which he has called a toxamin, and partly because they lead to increased growth without at the same time supplying to bone a sufficiency of calcium, phosphorus, and calcifying vitamin. Those cereals which are relatively rich in calcium and phosphorus, such as oatmeal and wheat germ, are specially rickets-producing. This work on the rickets-producing effect of cereals has recently been further confirmed by György (1933), who found that maize meal was more potent in this respect than oatmeal. These discoveries have an obvious bearing on the treatment of rickets in children.

In the treatment of osteomalacia Maxwell (1930) states that given cod-liver oil, good food, and sunlight, the majority of the patients will slowly recover. He finds that most cases require 1–2 oz. of cod-liver oil daily, together with calcium lactate. The cure is permanent, provided the patient takes reasonable care. Some of his patients were found to be well after seven years; others stood the test of a further pregnancy without recurrence of symptoms. So far as China is concerned, this is not the whole story. Poverty is widespread, and until China gets rid of banditry and civil war osteomalacia will remain. What the Chinese want to-day is flocks and herds, milk and meat, with security of life and property (Maxwell, 1923). In India the problem is much more difficult, and emancipation of women must see the end of the purdah system before modern knowledge can be applied as it should.

---

* Lecture to the Torquay and District Medical Society on March 7th.

Maxwell (1935) has proved that rickets may occur in antenatal life. Working in China, he took radiograms of the bones of the new-born babies of osteomalacic mothers and demonstrated the typical changes of rickets in the metaphyses. It is of some importance, too, that babies of osteomalacic mothers do get rickets in postnatal life. There is no doubt that the old reports denying the coexistence of osteomalacia and rickets in the same areas are fallacious. Rickets has now been found plentifully in children, where osteomalacia is well known, in Japan (Ogata, 1913), China (Tso, 1924) and India (Green-Armytage, 1928).

Mention must here be made of the influence of diet on the structure of teeth. The occurrence of hypoplasia of the teeth, with defects both in the enamel and the dentine, has been recognised for years in rickets. Such malformations are by no means exclusively of rickety origin, for they occur in other disturbances of metabolism. According to a number of authors a lack of vitamin C leads, in guinea-pigs, to defective teeth (Zilva and Wells, 1919). The changes here commence in the pulp, the dentine being affected later. M. Mellanby (1928) has studied the teeth in dogs and in children. On a diet deficient in vitamin D, particularly if it was rich in rachitogenic cereals as well, the dogs developed severe hypoplasia of the teeth, whereas the controls receiving antirachitic substances in addition had sound teeth. She showed that in children energetic administration of cod-liver oil or irradiated ergosterol lessened the incidence of such defective teeth and of the caries to which they are subject. Further, even in the presence of defective teeth, caries occurred far less readily in children so treated (Mellanby and Pattison, 1928). In two groups of school-children, one group treated and the other not, the average incidence of caries was respectively 1·4 and 5·1. M. Mellanby showed that in dogs dental defects can occur in the first dentition, as a result of a deficiency of vitamin D in the food of the mother. Walkhoff (1929) has demonstrated in guinea-pigs a similar effect in the case of vitamin C.

Aphosphorosis and Osteomalacia in Animals

In recent years veterinary pathologists have investigated the skeletal diseases of domesticated animals, using the experimental method. Their work has thrown considerable light upon disorders of nutrition in general.

Styfsiekte, or "stiff-sickness," is a disease of South African cattle in which the animals develop an intense craving for bones, a symptom which is termed osteophagia. It shows itself in retardation of growth, stiffness, lameness, and spontaneous fractures. In the affected areas the soil and grass are deficient in phosphorus, so that hay may contain less than one-fifth the normal amount of phosphorus. Theiler, Green, and du Toit (1927) have reproduced experimentally "aphosphorosis," or clinically recognisable phosphorus deficiency disease, and have shown not only that it is identical with the naturally occurring South African disease, but also that its histological characteristics are those of osteomalacia or rickets. Sunlight is apparently unable to prevent its occurrence, but the routine use of bone meal abolishes osteophagia and styfsiekte and leads to an increase of the milk yield of cows, better calves at birth, and more rapid growth of young stock.

Theiler (1934) has also been able to confirm the view that the disease known as "equine osteomalacia" is not strictly osteomalacia at all, but osteodystrophia fibrosa, a disease more comparable to osteitis fibrosa of man. A survey of the experimental data makes it clear that the main cause of this disease is a diet of low-calcium, high-phosphorus content. The bone diseases of domesticated animals, rickets, osteomalacia, and osteodystrophia fibrosa, may all be regarded as dietary deficiency diseases. Deficiency of phosphorus leads to rickets and osteomalacia in cattle, excess of phosphorus and inadequate calcium to osteodystrophia fibrosa in equines, and deficiency of vitamin D to rickets and osteomalacia in dogs. The significance of mineral balance, however, is not the same for all animal species. They differ in their physiological reactions. A ration which produces osteodystrophia fibrosa in the horse does not produce it in cattle. Indeed, that disease is apparently unknown in the bovine.

Xerophthalmia

It is recorded in the Papyrus Ebers that night-blindness was recognised and treated with liver a thousand years before the time of Hippocrates. Keratomalacia was first clearly described in England in 1827, and it soon became well known in emaciated infants with diarrhœa. In 1850 a French country doctor in the neighbourhood of Bordeaux cured night-blindness in a young boy by using cod-liver oil (Despont, 1858). Between 1854 and 1857 he treated what he called epidemics of this condition occurring in peasants. He was struck by the specific action of cod-liver oil, and wondered to what constituent this was due. He came very near to the truth when he pointed out that the effect could not be due to its ordinary food value because it worked in such small doses. He records cures in 14 cases, in which the patient was better usually in three days, and always before the tenth day. He afterwards found the condition to occur in seamen on long voyages and in soldiers in barracks. In 1863 Bitot described a lesion of the conjunctiva peculiar to xerophthalmia. He was working in a foundling hospital in Bordeaux. The lesion consisted of whitish or yellowish foam-like spots resembling mother-of-pearl situated on the bulbar conjunctiva just outside the cornea. They were quite small, and looked as if they would easily brush off with a movement of the lids, but actually remained unchanged when the lid was gently rubbed over them. He found that their appearance preceded night-blindness, and he recorded their complete disappearance after the sight returned to normal.

Xerophthalmia is still common in many countries including Russia, India, China, Japan, Central America, and Labrador. It was widespread in Germany, Austria, and Denmark during the time of privation following the war and during the war. In 1917 Bloch showed that many infants in Copenhagen suffering from general malnutrition and xerophthalmia could be cured of both by the use of cod-liver oil. There is a marked seasonal incidence, nearly all the cases ocurring in March and April. The first eye symptoms are dryness of the ocular conjunctiva which becomes wrinkled and shrunken. Later Bitot's spots appear. The disease rapidly spreads to the cornea, which becomes dull, uniformly hazy, and insensitive. Later a greyish necrosis of the sets in, followed by ulceration. This is called keratomalacia.

Denmark exports most of its dairy products, especially butter. Early in the war butter fetched high prices and the Danes were left with margarine and lard, substances deficient in vitamin A. By the end of 1917 xerophthalmia assumed grave proportions, and the State intervened, taking over control of all butter, which was rationed and sold at prices within the reach of all. A sharp decline in the incidence of xerophthalmia followed immediately. Nevertheless, there are in Denmark to-day large numbers of people who were blinded as babies in the war. Thus Blegvad (1924) collected 601 cases occurring between 1909 and 1920. Of these cases 21·5 per cent. died, 27 per cent. became blind, and 24 per cent. had serious impairment of vision in both eyes.

This knowledge comes home to us to-day when we realise that night-blindness has been found to occur in the Durham coal-fields (Spence, 1931). Boys affected complain that as dusk approaches they cannot see to compete successfully in play with their companions in the street. Bitot's spots form the most characteristic sign of the disease. All signs and symptoms are found to disappear on adding 10 c.cm. of cod-liver oil to the diet daily. Neither irradiated ergosterol nor ultra-violet irradiation has any effect. The curative substance is undoubtedly vitamin A.

The experimental work of Tansley (1931) affords an explanation of night-blindness as it occurs in vitamin-A deficiency. She followed the course of the regeneration of visual purple in normal and vitamin A-deficient rats. The visual purple was extracted from the retina by a dilute solution of digitonin and quantitatively estimated by a photographic method. She was able to show that the retinas of the deficient rats contained in every case subnormal amounts of the visual purple.

Milk, cream, butter, cheese, liver, spinach, and carrots are excellent sources of vitamin A, and a great many other common foods contain appreciable amounts. Of vitamin A we almost certainly know the structural formula. Chemists appear to be agreed that it is an alcoholic derivative of about half of the carotene molecule. It has not been isolated in the pure state, nor has a crystalline derivative so far been prepared. The daily requirement for health is unknown, but has been estimated as less than 2 mg. (Underhill, 1934).

There is some evidence that a diet devoid of vitamin A results in diminished resistance to infection, but much work remains to be done in order to establish in a more precise way this relationship between nutritional defect and susceptibility to infection. In a large-scale experiment Green and Mellanby (1928) found infective foci almost without exception in young rats brought up on diets which were complete except for vitamin A. There is also experimental evidence that vitamin A may successfully prevent the infection of animals with different bacteria (Lassen, 1932). Its most striking action is observed when the infection takes place through an epithelial surface. Large doses of vitamin A have been used in the treatment of puerperal sepsis by Mellanby, of measles by Ellison, and of pneumonia by Donaldson. Ellison (1932) tested the effects of a vitamin concentrate rich in vitamin A and D on 300 cases of measles under the age of six, using another 300 cases of similar age as controls. The mortality in the vitamin-treated cases was 3·7 per cent., and in the control cases 8·6 per cent. The vitamin treatment lowered the mortality of cases with pulmonary complications, but did not lower the otological and cutaneous complications. Donaldson (1930) reported a mortality of 8 per cent. amongst 200 cases of pneumonia receiving vitamin A; 400 control cases had a mortality of 13 per cent. It is impossible to say whether this difference is significant, and it is a fact that not all observers have been able to confirm these results.

The observation of Mellanby (1934) that peripheral nerves show signs of degeneration when the diet is deficient in vitamin A has led him to review the evidence in favour of the accepted causes of certain nervous diseases, and to suggest that the nervous lesions are really due to vitamin-A deficiency. In animals he has shown that vitamin A has a protective influence against the appearance of nervous lesions in poisoning by ergot, and he has suggested that the nervous lesions of lathyrism, pellagra, and subacute combined degeneration of the cord may be due to a similar deficiency. Only future work can show how far this is the case.

Beri-beri

At least five B-vitamins have now been identified (Peters, 1934). Of these 3, 4, and 5 are interesting scientifically, but so far they have not been shown to have any clinical application; 4 is necessary for the well-being of rats and 3 and 5 for the well-being of pigeons. There is little, if any, definite proof that a shortage of B-vitamins ever occurs in this country. Deficiency of vitamin B_1 gives rise to beri-beri, a disorder characterised either by multiple peripheral neuritis or by gross œdema, often with heart failure. Beri-beri occurs principally among the rice-eating populations of Japan, the Malay Peninsula, the Dutch Indies, and the Philippine Islands. It may also break out under conditions of starvation, famine, or siege, as it did in the British armies on Gallipoli and at Kut.

In 1928 Bray found large numbers of mysterious deaths under 1 year in the island of Nauru, a mandated territory in the Pacific administered by the Commonwealth of Australia. Forty-five per cent. of the babies born in a year died before the age of 12 months. This was due to infantile beri-beri brought about by a deficiency of vitamin B_1 in the diet of the mother. Inquiry showed that certain white officials had forbidden the native his toddy. This is a fermented sap made from the coconut, and contains large quantities of vitamin B_1. The mothers of Nauru, consuming the milled cereals offered them by the traders, had a greater need of toddy than when living on their original vegetable diet, and when it was denied them their babies died. It is probable that most strong native beers are valuable foodstuffs owing to their high content of yeast. Had it not been for the presence of a wide-awake medical officer the babies would still be dying, and yet another South Sea island would be undergoing a mysterious depopulation. Fortunately timely dietary reforms were made with excellent results (Bray, 1934). Vitamin B_1 was added to the mother's diet and every infant from birth was given each day a teaspoonful and a half of toddy yeast—the yeast which grows in the sap of the coconut spathe. As a result the infantile death-rate dropped from 450 per 1000 births to 92 per 1000 within a year, and this figure was maintained during the five succeeding years, while the birth-rate increased by 60 per cent. During six years after the introduction of these measures there was not a single maternal death in an average of 65 births per year.

The distribution of B-vitamins in nature is wide, and they are not easily destroyed by cooking. Eggs, yeast, and wholemeal bread are potent sources. Vegetables, fruit, milk, and animal organs all contain good supplies, and meat less but still appreciable amounts. Vitamin B_1 has been obtained in a crystalline and probably nearly pure form by several investigators. There is some difference of opinion as to the purity of the various crystalline products, which have been made from rice polishings, wheat germ, and yeast. Details of the structure of the molecule are at present largely a matter of speculation.

Pellagra

First observed more than 300 years ago, pellagra has now been described in many countries, including Italy, Spain, Rumania, and Egypt. It was not recognised in the United States until 1908, but since that date hundreds of thousands of cases have been recorded, principally in the southern States. It is characterised by symmetrical skin eruptions, sore mouth, diarrhœa, subacute combined degeneration of the cord, and ultimately mental symptoms. It is a disease of poor people subsisting usually on a maize diet. Its occurrence in populations eating mainly wheat or rice is something of a rarity. The association of pellagra with maize consumption led to two theories, the first that the disease might be caused by a lack of protein of high biological value, and the second that it might be due to a toxic substance derived from maize. The proteins of maize have been shown to consist to the extent of 58 per cent. of zein, the notoriously incomplete protein lacking the important amino-acids tryptophane and lysine. The work on zein of Osborne and Mendel (1913) shows conclusively that young animals fed on diets containing zein as the sole source of protein could not maintain their weight unless tryptophane was added, and were unable to grow unless lysine was given. The observed good effect on pellagra of adding meat, milk, and eggs to the diet can therefore readily be explained as due to the advantage of giving a richer variety of essential amino-acids.

More recently it has been shown that yeast extracts have a dramatic effect on the symptoms and signs of pellagra. The results of experimental work with rats enabled Goldberger (1926) to identify the pellagra-preventive substance in yeast as vitamin B_2. To fit these facts Chick (1933) has formulated the following theory: pellagra is caused by a toxic substance derived from the maize diet, which can be corrected by sufficient "good" protein, or perhaps by sufficient vitamin B_2 (which is found to accompany the "good" proteins).

It has recently been suggested (Minot, Strauss, and Cobb, 1933) that alcoholic polyneuritis may be regarded as a deficiency disease analogous to the neuritis of beri-beri. The alcohol addict tends to neglect other foods, and can rarely be said to enjoy a good diet; in addition absorption is impaired in the damaged intestinal tract. Alcoholic pellagra is frequently seen in the United States, and the connexion between alcoholism and pellagra has been recognised in Rumania (Aykroyd, 1933) in districts where pellagra is endemic. Here the possibility of a toxic factor in maize should not be overlooked, for alcoholic pellagra became much commoner in America during the Prohibition period in which illicit whisky was distilled principally from maize products. Further, the disease is almost unknown among alcohol addicts in Europe in districts where spirits are distilled from barley or cereals other than maize.

Pellagra is rare in this country. The cases met with are usually secondary to gastro-intestinal disease. In 1925 Bender described three cases of pellagra secondary to lesions of the stomach interfering with nutrition. This paper indicates clearly for the first time the sequence of events and the apparent gastro-intestinal contributing cause of the pellagra. Especially is this true of one of his patients who developed pellagra while being fed through a jejunostomy tube for the cure of a non-malignant gastric ulcer. In 1930 Ellis noted the occurrence of pellagra secondary to tuberculous enterocolitis, with severe diarrhœa in a boy of nine. Simpson (1935) has recorded the complete cure of a case of secondary pellagra by the use of a concentrate of vitamin B_2 prepared from egg-white. The patient was a woman, aged 46, who had developed secondary pellagra two years after an extensive partial gastrectomy for duodenal ulcer.

The distribution of vitamin B_2 among natural foodstuffs is similar to, though not identical with, that of B_1. There are many quantitative differences. The embryo and bran of cereal grains are rich sources of B_1 but are poor in B_2. Egg-white is the one foodstuff yet discovered which contains B_2 unaccompanied by B_1 (Chick, 1930). Vitamin B_2 has lately been divided by Kuhn (1933) into two fractions, one of which is crystalline and is believed to be one of the flavines. Ovoflavine from egg-white is a yellow substance with a green fluorescence, and is highly sensitive to light, a point which may be of importance in relation to the light sensitivity of pellagrins. This work is a striking development of the discovery of vitamin B_2 in egg-white.

Scurvy

It was common knowledge, even in the fifteenth century, that scurvy occurred after deprivation for long periods of fresh foodstuffs. In 1779 the Channel Fleet had 2400 men disabled by the disease after a cruise of only ten weeks. In 1795 introduction of lemon juice into the British Navy as a routine ration led to the disappearance of scurvy amongst sailors. We now possess exact knowledge as to the vitamin C content of various foodstuffs. The juices of lemon, orange, and onion are very rich sources of vitamin C; swede and tomato come next, whereas lime juice, grape juice, potato, carrot, and milk are low down in the list. Vitamin C is destroyed by heat, by oxidation, and by alkali. An acidic substance like lemon juice retains its antiscorbutic activity for a long time, even in the presence of atmospheric oxygen. It should be realised that the heat used in the manufacture of dried milk destroys vitamin C, and that green vegetables should not be cooked with sodium carbonate or bicarbonate.

The story of the chemistry of vitamin C is singularly full of paradoxes and dramatic surprises. Up to four years ago it was generally agreed to be the least stable and the most elusive of all the vitamins. Lemon juice has long been known to possess a remarkable chemical reducing property, but this was always dissociated from the properties of vitamin C. In 1928 Szent-Györgyi isolated from the suprarenal gland hexuronic acid, and concluded that it is identical with "the reducing substance present in active vitamin-C concentrates." In the same year Tillmans made use of this chemical reducing property—the indophenol reduction test—to distinguish fresh from stale or artificial fruit juice. In 1930 he showed that the indophenol titre generally runs parallel with vitamin-C activity. In 1932 he postulated the identity of vitamin C with Szent-Györgyi's hexuronic acid. Later in the same year Waugh and King isolated from lemon juice a substance which closely corresponded with the hexuronic acid of Szent-Györgyi, and showed that daily quantities of 1 mg. prevented scurvy in guinea-pigs. The identity of this hexuronic acid with vitamin C has since been confirmed, and in 1932 Haworth and Hirst synthesised it and called it ascorbic acid to distinguish it from other hexuronic acids.

In the green pods of the Hungarian paprika, *Capsicum annuum*, Szent-Györgyi discovered what is now the richest known source of vitamin C. These pods contain weight for weight four times as much vitamin C as orange or lemon. In 1933 Parsons showed that ascorbic acid would cure infantile scurvy, and Schultzer that it would cure adult scurvy. The protective dose for an adult is less than 50 mg. a day. One gramme would suffice for more than three weeks. In the summer of 1934 the British Graham Land Expedition left England for the Antarctic and the

Oxford University Ellesmere Land Expedition for the Arctic. In each case the equipment included small tubes containing tablets of ascorbic acid for the use of sledging parties. Clearly the problem of transport and storage of vitamin C for remote expeditions is completely solved.

Scurvy is characterised by changes in capillary endothelium, leading to hæmorrhages, and by diminished activity of hæmopoiesis. Thus anæmia may occur apart from hæmorrhage. This anæmia responds to vitamin C and the response is specific, for it does not occur to iron or liver (Mettier, Minot, and Townsend, 1930). In infantile scurvy the bones are affected. In addition to subperiosteal hæmorrhage there is cessation of osteogenetic activity, arrest of endochondral ossification, but no deficiency in the calcification of the matrix of cartilage. These changes result in osteoporosis, sometimes with spontaneous fracture.

Occasionally scurvy actually comes on while the patient is under medical treatment. Thus Davidson (1928) reports two cases under treatment for gastric ulcer, one by the Sippy method and one by the Lenhartz method. In both cases scurvy resulted. Rapid recovery occurred when orange juice was added to the diet.

Endemic Goitre

It has been established by recent observations that in certain parts of the world there is a danger of human beings and animals failing to secure in their food a sufficient supply of iodine. The human thyroid gland contains up to 15 mg. of this element, representing an iodine content 50 times as great as that of any other tissue. The daily iodine requirement of an adult is at the most 0·05 mg. In 1926 Harington established that thyroxine was a phenyl ether of tyrosine containing four iodine atoms. He then synthesised it. A lack of iodine in the diet prevents the formation of thyroxine, and leads to hyperplasia and enlargement of the gland.

In the Yellowstone River Valley there was at one time a loss of approximately 1,000,000 young pigs and numerous lambs, calves, and colts each year as the result of thyroid disease. Owing to the shortage of iodine in the soil, sows had goitres and gave birth to litters of dead hairless pigs showing great enlargement of the thyroid gland. This most serious problem in animal production was studied by Smith (1917) who found that it was only necessary to administer sodium or potassium iodide to the pregnant animals in order to prevent the condition.

Keith (1924) studied the problem of goitre in the Pemberton Valley, British Columbia. At the lower end of this valley is an Indian reserve, peopled by about 150 Indians. In the Indian village no sanitation has ever been attempted, but salmon is eaten in quantity. No case of goitre has ever been recorded among these Indians, the reason being that the salmon provide iodine obtained from the sea. White settlers noticed as they ascended the valley that the incidence of goitre and fœtal athyrosis increased in their animals. All hens, ducks, and turkeys brought into the valley appeared to thrive but their eggs, though producing embryos, failed to hatch out. Almost every woman and many of the men coming into the valley would develop goitre within a few months or a year. All the babies born in the district had goitre. The use of iodine was recommended and it acted in a miraculous way; all the goitres disappeared from the animals and no further trouble in rearing stock or fowls occurred. Any resident with a goitre took a little iodine until it disappeared. The same effect was obtained by drinking the milk of cows receiving iodine. It cost $2 a year for iodine to keep 100 cattle, 12 horses, 30 pigs, 200 chickens, and all their progeny free from goitre. It is now impossible to find a goitre anywhere in the whole valley, either in animal or in human being.

In at least five regions where goitre is endemic contrasts of the iodine content of the diet with the incidence of goitre have been made for goitrous and non-goitrous districts. There is complete agreement between these surveys—namely, that a striking inverse relationship exists between the content of iodine in the diet and the proportion of goitrous individuals among the total population. The evidence associating undue lack of iodine in the diet with prevalence of endemic goitre strongly suggests a causative relationship between the two, but it does not afford final proof that lack of iodine can be the sole cause of this goitre. There is good evidence that such a goitre can arise from other causes, but there is overwhelming evidence that in communities where the diet contains a sufficiency of iodine such endemic goitre is extremely rare.

In certain regions in the Himalayas McCarrison (1927) has found that drinking-water relatively rich in iodine does not prevent the occurrence of endemic goitre in the presence of a high degree of bacterial impurity. Further the substitution of a bacteriologically pure for an impure water has caused the rapid and complete disappearance of the disease from a place where it has been endemic for 70 years, although the new water-supply contains less iodine than the old. He claims to have induced goitre in man by the administration of sediments from contaminated drinking-water and to have cured it by intestinal antiseptics. Animal experiments have suggested a goitrigenic action of cabbage. The active material was believed to be a glucoside. It is known that cyanides are components of the glucosides in certain vegetables. Hence Marine (1932) injected various organic cyanides into young rabbits and goitres were produced.

It seems therefore that endemic goitre can arise from more than one cause, including lack of iodine, some goitrigenic factor in cabbage, and a water-borne infective agent. The important thing is that iodine acts as a shield against endemic goitre, and iodine prophylaxis is the most important preventive measure. This usually takes the form of legislation ensuring the addition of minute amounts of iodine compounds to table salt. The proportion used in Switzerland is five parts (of potassium iodide) per million, and in New Zealand four parts per million. At the present time iodised table salt in different countries varies widely in its iodine content. Thus that used in Canada contains 20 times as much iodine as the Swiss supplies. The excellent results of Swiss prophylactic measures suggest that the proportions used in Switzerland and New Zealand are of the right order.

Nutritional Anæmias of Infants

An anæmia of hypochromic type occurring equally in both sexes has been known at various times as pseudo-chlorosis of infants, alimentary anæmia, and cow's milk anæmia. It is due at least partly to inadequate iron intake. Milk is notoriously poor in iron, cow's milk more so than human milk.

Mackay (1931) has shown that 40 per cent. of breast-fed babies and 70 per cent. of artificially fed babies in the hospital class are anæmic. She was able to cure this anæmia by adding to their feeds iron and ammonium citrate. A solution of 1½ grains to a teaspoonful of water was prescribed and instructions given to the mother to add this to the feeds, beginning with a few drops and increasing gradually until a teaspoonful was given with each feed. Gradual increase of the iron dosage is essential, otherwise the infant may develop colic, vomiting, or diarrhœa, and the treatment might then unfortunately be stopped. The mother must also be warned that the stools will be dark in colour. Certain proprietary brands of infant foods are now available in which iron and ammonium citrate has been incorporated in suitable amounts.

The presence of anæmia in an infant reduces its resistance to such bacterial infections as otitis media or pyelitis. If such infection is of sufficient severity to lead to systemic disturbances, this in turn is likely to increase the severity of the anæmia. In such ill babies it is necessary to begin the administration of iron very gradually, but ultimately doses of grs. 5 to 10 of iron and ammonium citrate daily should be given. There seems little doubt that the prophylactic administration of iron at an early age leads to a considerable diminution in child morbidity, and its use should be encouraged, especially among artificially fed infants.

Anæmia is perhaps less common in the babies of the wealthier classes. There would be little need for iron therapy in infants if all women could be given an adequate diet during pregnancy, and if the milk and cereal diet of infants were to be supplemented at the age of nine months with meat, eggs, and green vegetables.

Idiopathic Hypochromic Anæmia

Recent studies have shown that idiopathic hypochromic anæmia is a deficiency disease (Kaznelson, 1929; Witts, 1931). The term hypochromic refers to the pallor of the red cells, or in other words to the low colour-index. In hypochromic anæmias the red marrow is actively producing red cells from normoblasts. The mechanism at fault is not the production of the red cell stroma but the provision of hæmoglobin to fill that stroma. This is the business of iron metabolism. Idiopathic hypochromic anæmia is probably due to a deficiency in the power of the alimentary canal to deal with iron in such a way as to make it available in hæmoglobin production. It occurs almost invariably in women, and especially in the childbearing period of life. The patient is tired and breathless, the ankles become puffy, the tongue may be sore, difficulty in swallowing may occur, the hair begins to fall out, and the finger-nails are brittle, tender, and often concave, a condition called koilonychia. Severe dyspeptic symptoms are occasionally found; amenorrhœa is common. Achlorhydria is frequently present. Its significance is seen in the fact that iron is best absorbed from an acid medium. The normal diet provides only a small positive balance of iron, especially for women who are menstruating and bearing children, and this soon becomes a deficit if the diet is poor and absorption is diminished by achlorhydria. In one-third of all cases the spleen is palpable. It is firm and soft, and never extends more than a few centimetres below the ribs. It completely recedes beyond the costal margin on repair of the anæmia.

In treatment large doses of iron must be given. Where the hæmoglobin figure is very low the patient must receive daily grs. 90 of Blaud's pill, freshly prepared and crushed. The idea that large doses of iron cause indigestion and constipation is by no means true. The dyspeptic symptoms are usually cured by Blaud's pill within six or eight weeks. When the hæmoglobin approaches the normal figure the dose of Blaud's pill can be reduced, though it is highly probable that the patient will require to take iron always. Iron and ammonium citrate may be given instead of Blaud's pill, but the effective dose is at least double. Iron should not be given by injection, owing to the long duration of treatment and the difficulty of giving adequate doses by this route. It is important to inquire into the diet, and to see that the patient takes plenty of meat, eggs, and green vegetables.

Pernicious Anæmia

Workers at the Harvard Medical School, in one of the most remarkable researches in the history of medicine, have shown that liver and stomach contain a principle curative in pernicious anæmia (Minot and Murphy, 1926), and that this principle is normally elaborated in digestion by the stomach and stored in the liver. The normal stomach secretes a ferment which is not hydrochloric acid nor pepsin nor rennin (Castle, 1929); this "intrinsic factor" acts on the proteins of the food to produce a hæmatinic principle which is necessary for the maturation of megaloblasts and the normal delivery of red cells into the circulation. Thus pernicious anæmia is a nutritional disorder of a special sort, and may be spoken of as a conditioned dietary deficiency disease. It is a disease of the stomach with secondary changes in the marrow, for in the absence of the hæmatinic principle the red cellular megaloblastic marrow remains functionally useless.

In the treatment of pernicious anæmia liver extract must be given by injection or by mouth, and the dosage regulated by the red cell count. Extract given by injection is at least thirty and perhaps fifty times as potent as that given by mouth. There is *no standard dose.* Severely anæmic patients may require 4 c.cm. for a few days, the dose being reduced to one-half or less of this amount after the maximum reticulocyte response has occurred. The red cell count must then be followed, and a maintenance dose determined which will keep it at five million. In many cases the maintenance dose is 1 c.cm. a week. The most important single fact about treatment is to give enough of the material. No ill-effects of overdosage are known. Infections, arterial degeneration, and hypothyroidism may interfere with the effect of the active substance, demanding increased dosage. Larger doses are required to improve or inhibit the progress of subacute combined degeneration of the cord than to permit of normal hæmopoiesis being maintained.

Minot (1935) has observed critically over two or three years 100 cases of pernicious anæmia, including 26 with advanced subacute combined degeneration of the cord. All of these were treated with injections of liver extract. In no case did a single objective sign in the nervous system become more marked, nor did any abnormal sign develop. Certain patients who were originally unable to walk became sufficiently improved to return to work. Failure to arrest the progress of neurological lesions, like failure to restore the blood to normal and keep it there, usually means that more liver is required. No claim is of course made that parenteral therapy acts in a different manner from oral therapy. Thus certain cases treated by Minot for over eight years by the oral method have shown no progress of their neurological lesions. It is possible in many cases to use adequate oral treatment, but, speaking generally, parenteral therapy is vastly superior, more convenient, and considerably cheaper; there is no doubt that it has come to stay.

Wilkinson (1935) has had excellent results using desiccated pig stomach, starting with an ounce a day until the blood count was normal and then reducing to perhaps a quarter of an ounce every three days. His cases have been observed over periods up to six years. Of 441 patients with pernicious anæmia, 92·5 per cent. were well, 3·4 per cent. had relapsed, 3·2 per cent. had died from other causes without anæmia, and 0·9 per cent. had died with anæmia. The nervous changes due to cord involvement responded well. None had developed subacute combined degeneration when under treatment, while those who already had cord changes had shown no increase of their nervous symptoms and indeed many bedridden cases had been able to return to work.

Anæmia following Gastric Operations

Changes in gastro-intestinal function affecting hæmopoiesis may result from operative interference with the stomach. We know quite definitely that both partial gastrectomy and gastro-enterostomy are occasionally followed by anæmia. At present it is impossible to say exactly why operative interference causes anæmia at all, and the evidence is insufficient to incriminate one type of interference rather than another. There is no apparent relationship between the degree of hypochlorhydria and the severity of the anæmia, nor between the occurrence of diarrhœa and the anæmia. We now possess an explanation of those cases which remain well without anæmia for many years after subtotal gastrectomy, for the work of Meulengracht (1935) has shown that the "intrinsic factor" is produced in the duodenum as well as in the pyloric portion of the stomach.

About 125 cases of anæmia following gastric operations have been recorded in detail. Of these 25 were cases of pernicious anæmia—15 following partial gastrectomy and 10 following gastro-enterostomy—and 100 were cases of secondary anæmia. There may be a long latent period between operative interference and the development of symptoms. Thus, in one series, the average period was six years and the longest fifteen years. It is quite well established that some patients develop hypochromic microcytic anæmia, and others hyperchromic megalocytic anæmia after the same operative procedure; the reason for this is difficult to see. Perhaps a study of the type of diet taken by patients during treatment for chronic ulcer both before and after operation might show that deficient intake of essential substances plays a part. Meat and green vegetables, so essential to normal hæmopoiesis, are too often lacking from the menu of such patients. Clearly accurate hæmatological studies over many years of a large series of cases following operation would be of great interest. The incidence of anæmia following gastric operations is so small that there is no need for alarm. Fortunately, too, when it does occur the results of treatment with liver or iron, according to the type of anæmia present, are satisfactory.

Idiopathic Steatorrhœa: Gee's Disease

In 1888 Samuel Gee published an account of the "cœliac affection," giving a clear description of a digestive disorder occurring in people of all ages, but especially affecting young children. He describes in detail the pale, bulky, and offensive stools, notes the occurrence of a similar disease in India, and points out the negative character of post-mortem examinations in fatal cases.

Recent investigations of Gee's disease suggest that the condition is due to a disturbance of gastro-intestinal function resulting in deficient production, absorption, or utilisation of one or more essential factors. To some extent it shares with pernicious anæmia the characteristics of a conditioned dietary deficiency disease. It occurs in patients born in Great Britain who have never resided abroad. One [illegible] features occur; fatty stools, with or without diarrhœa; dilatation of the colon, tetany, osteomalacia, infantilism, anæmia, and skin lesions sometimes resembling pellagra. In a group of 15 cases recently investigated (Bennett, Hunter, and Vaughan, 1932) steatorrhœa and disturbances of calcium metabolism were alone common to the whole group. Changes in the skeleton were found in all cases investigated. Radiograms showed osteoporosis and often florid rickets. In 3 cases histological examination of portions of bone showed osteoporosis and osteomalacia. Tetany occurred in 14 cases and clubbing of the fingers in 9.

1919, xc., 505

The blood count was either normal or showed (i) hypochromic anæmia, (ii) hyperchromic megalocytic anæmia, or (iii) erythroblastic anæmia. No relation between the type and severity of the anæmia and other symptoms was established. In 13 cases out of the 15 the serum calcium was low and in 10 the plasma phosphorus was low or normal. Calcium balance estimations showed high figures for fæcal output and very low figures for urinary output.

Treatment presents great difficulties. The steatorrhœa must be controlled by a low-fat diet. The best way to secure a low-fat, high-calcium diet is to use skimmed milk together with Casec or some other preparation of calcium caseinate. Where tetany occurs calcium lactate must be given fasting, in doses of 5 grammes three times a day. Vitamin D in a solid medium should be given in every case where there are clinical or radiological signs of rickets, osteomalacia, or osteoporosis. General ultra-violet irradiation is also of value. These measures may relieve bone pain, though any relapse of diarrhœa is liable to interfere with this good effect. Treatment of the anæmia must depend upon proper examination of the blood. Where it is hypochromic in type, large doses of iron must be given until the hæmoglobin figure reaches normal. This may occur after the use of Blaud's pill grs. 30 three times a day for eight weeks or more. Where hyperchromic megalocytic anæmia is present, injections of an active preparation of liver must be repeated until the red cell count remains at five million. The proper maintenance dose must then be worked out; it is often 1 c.cm. per week. As in the case of tropical nutritional anæmia (Wills, 1931) marmite by mouth may be used instead of liver, as much as 12·0 g. daily usually being required (Vaughan and Hunter, 1932). Whatever the form of the anæmia, it is essential to remember the importance of adequate dosage.

There is no doubt that the results of treatment are more disappointing in the adolescent and adult cases than appears to be the case in children suffering from cœliac disease. Some cases respond satisfactorily and remain well under treatment. In others all that is accomplished is the alleviation of one or more symptoms and the temporary arrest of the downward progress. It is none the less gratifying to see the great improvement in the anæmia of many of the cases, and the recovery from the pain and disability of osteomalacia in others. Often there is a great change for the good in the mental outlook of a dwarfed, crippled, anæmic patient as he is gradually relieved from his disabilities, especially the anæmia. Unfortunately one group of physical signs and symptoms may clear up completely, and yet the patient may die of inanition. Thus the pellagra-like skin lesions may heal under treatment with marmite yet relapses of diarrhœa may result in the death of the patient, the skin remaining normal.

Until quite recently there were those who held that the conception of vitamin deficiencies wa[illegible] that the chemist would never identify accessory factors in food, and that pernicious anæmia was due to changes in the bone-marrow analogous to malignant disease and therefore quite incurable. Plain answers can now be provided. International standards and units have been adopted for vitamins A, B_1, C, and D, and vitamins B_1, B_2, C, and D exist in crystalline form. It is now a commercial possibility starting with a pennyworth of starch to synthesise from it a gramme of ascorbic acid and to sell this for a shilling, so that the explorer can carry tablets which protect him from scurvy at the cost of threepence a week. The patient with pernicious anæmia can be kept alive and well by weekly injections of liver extract costing sixpence.

However, in spite of so much ground gained our knowledge is still imperfect. Recent studies suggest that nutritional failures in man are often more complicated than the results of animal experiments would indicate. Thus in the case of vitamins there is already some evidence that nutrition of the skin depends on B_2 and A, of nerve tissues on B_1 and A, and of teeth on D, C, and A. With regard to physiological needs, we are ignorant as to the most desirable diet in childhood, at puberty, and during pregnancy, and we know little as to the optimum requirement of first-class protein and of vitamins. In pathological states such as idiopathic steatorrhœa and sprue we have only hints as to the truth. The conception of conditioned dietary deficiency diseases is clearly important, but its development is hampered by our ignorance on the whole question of absorption from the gastro-intestinal tract.

MANDELIC ACID IN THE TREATMENT OF URINARY INFECTIONS*

By M. L. ROSENHEIM, M.B. Camb., M.R.C.P. Lond.
RESEARCH ASSISTANT, OBSTETRIC UNIT, UNIVERSITY COLLEGE HOSPITAL; AND ASSISTANT MEDICAL REGISTRAR, WESTMINSTER HOSPITAL, LONDON

THE ketogenic diet, first introduced by Clark[1] and Helmholz[2] in 1931 for the treatment of urinary infections, has been widely adopted and has proved highly successful, especially in cases in which there is no underlying urinary obstruction. The treatment suffers however from the objection that it requires rigid supervision both of the patient and of the diet; it is therefore unsuitable for use outside an institution, and patients with chronic infection of the urinary tract are not ill enough to require in-patient treatment. Moreover the ketogenic diet is not pleasant to take, and in order to be effective it must upset the normal physiological state of the patient.

Fuller (1932)[3] showed that the effective bacteriostatic factor in the urine of patients on the ketogenic diet was β-hydroxybutyric acid and that this acid exercised, in vitro, a strong bacteriostatic action below pH 5·5. This has been confirmed by Wells (1934).[4] The administration of β-hydroxybutyric acid by mouth under normal metabolic conditions is ineffective in the control of urinary infections since the acid is completely oxidised; it has, however, been administered orally by Fuller and Colebrook[5] to reinforce the effect of a dietary ketosis and it may have a limited use as a bladder wash-out in cases of chronic cystitis. Fuller has shown that aceto-acetic acid and

TABLE I.—BACTERIOSTATIC EFFECTS OF VARIOUS ACIDS ON GROWTH OF B. COLI IN VITRO

Acid.	Formula.	Max. pH at which 1 per cent. concentration has been found effective.	Min. concentration found to be effective at pH 5.	Remarks.
		pH.	Per cent.	
β-hydroxybutyric acid .	$CH_3.CHOH.CH_2.COOH$	5·5*	0·3*	The effective factor in the ketogenic diet.
β-hydroxypropionic acid	$CH_2OH.CH_2.COOH$	5·5*	—	Bacteriostatic in vitro.
Lævulinic acid	$CH_3.CO.CH_2.CH_2.COOH$	6·0	0·25	Bacteriostatic in vitro.
Lactic acid	$CH_3.CHOH.COOH$	No effect at pH 5·4	—	—
Pyruvic acid	$CH_3.CO.COOH$	No effect at pH 5·0	—	—
Benzoic acid	$C_6H_5.COOH$	6·0	—	Bacteriostatic in vitro.
Hippuric acid	$CH_2(NH.OC.C_6H_5).COOH$	5·0 (No effect at pH 5·6)	—	Slight bacteriostatic power.
Benzoylacetic acid ..	$C_6H_5.CO.CH_2.COOH$	8·0	0·1 effective at pH 5·3	Highly bacteriostatic in vitro.
β-phenyl-β-hydroxypropionic acid.	$C_6H_5.CHOH.CH_2.COOH$	—	0·2 effective at pH 5·5	Bacteriostatic in vitro.
Mandelic acid	$C_6H_5.CHOH.COOH$	6·2–6·3	0·4 effective at pH 5·1–5·2	Bacteriostatic in vitro.

* Concentrations calculated as per cent. sodium salt.

acetone have slight bacteriostatic powers, in vitro, compared with β-hydroxybutyric acid.

The possibility suggested itself that a keto- or hydroxy-acid might be found which would combine effective bacteriostatic power with resistance to oxidation in the body. Such an acid, if excreted unchanged in the urine and if non-toxic, should be able to replace the ketogenic diet. As a preliminary test, a number of acids were compared with β-hydroxybutyric acid in respect of their bacteriostatic powers in vitro. The results are summarised in Table I.

Preliminary Experiments

all experiments urine was used as the medium. sterilised by filtration and the concentration acid to be tested and the pH were adjusted g to the experiment. The acid content er adjusted before filtration by adding a quantity of the acid followed by the equiva- nt of NaOH, or after filtration by adding d volume of a filtered neutralised solution in urine.

aining 5 c.cm. of the medium were used in ents and the pH was adjusted by adding quantity of HCl or NaOH.

volume (usually 0·1 c.cm.) of a culture or of *B. coli* was added and the numbers of n. present at the start, and after 24 hours' 7° C., were estimated by plating out the cultures, either undiluted or in dilutions of 1 in 100, 1 in 10,000, or 1 in 1,000,000 in blood agar plates. The plates were layered with agar after cooling to prevent spreading, and the colonies on the plates were counted after 24–48 hours' incubation.

The cultures of *B. coli* used were the two stock laboratory cultures and also various strains of *B. coli* isolated from the urines of infected patients.

Of the aliphatic acids tested, β-hydroxypropionic and lævulinic acids were found to possess satisfactory bacteriostatic powers. It seemed unlikely that the former could escape oxidation in the body and it was therefore not further investigated. Lævulinic acid, reputed to be excreted unchanged by dogs (Weintraud,[6] 1894), was administered to two patients with pyelitis of pregnancy but with no good results. Of the aromatic acids, benzoylacetic and mandelic acids were selected for further trial. β-phenyl-β-hydroxypropionic acid was excluded owing to its inaccessibility, whilst it is known that benzoic acid given by mouth is excreted in the urine as hippuric acid, the bacteriostatic powers of which are inferior to those of the other aromatic acids investigated.

Benzoylacetic acid had the strongest bacteriostatic powers of any of the acids tested. Three grammes of the acid were given to a normal man with no toxic effects. The acid was apparently rapidly excreted in the urine which gave a strongly positive ferric chloride

c.cm. (1/10,000 dilutiions have been observed in the
c.cm. (1/1 mill. dilutio delic acid. It is of course neces-
he ketogenic diet, to control the urinary pH by estimation with methyl red. It seemed possible, since mandelic acid is foreign to the body and is not metabolised, that the treatment might cause renal irritation, and specimens of urine have been repeatedly tested to note any occurrence or increase of albuminuria. In two cases, granular and hyaline casts and an occasional red cell, previously absent, were found in the urine following improvement on mandelic acid therapy; in both cases the treatment was stopped, and within a few days the casts disappeared from the urine. One of these cases was a woman, aged 24, who had infection of one urinary tract, the other kidney having been recently removed for hydronephrosis. She had had some renal infection as a child. The other case, a girl aged 12, had had chronic pyelitis for over a year and was receiving mandelic acid while in hospital for treatment of a chronic abscess. She was one of two cases in which an increase in albuminuria was noted. In the other case, the reappearance of albuminuria was probably not due to the mandelic acid (see report of Case 4). Mandelic acid has been given to a patient who was known to have albuminuria following renal disease in pregnancy, and there was no evidence of increased renal damage; it has been given daily over a period of one month to a case of pyelitis without producing any albuminuria, and it therefore is not a general renal irritant. The exact significance of the casts in these two cases is thus not yet clear, but their occurrence must be taken as a warning that, at present, care should be exercised in the use of mandelic acid in the presence of any renal impairment, and that in all cases a watch should be kept on the urine. No other complications due to the acid have been noted, beyond some buzzing in the ears and temporary deafness of which two or three patients have complained.

Though Pribram (1904)[9] showed that
was an effective diuretic in animals
to its use in clinical medicine has be

the purpose described in this paper it can readily be used in ambulatory treatment, and it does not upset the patient. The treatment is not expensive. One kilogramme of the acid, which is an ordinary commercial product, costs at present 70*s.*, so that treatment for ten days with 12 g. a day costs about 8*s.* 4*d.* This is not more expensive than the ketogenic diet which requires not only special foodstuffs but also expert preparation.

CASE REPORTS

CASE 1.—A doctor, aged 64, had suffered from chronic cystitis for over a year. He had had several acute attacks, with pain, shivering, marked frequency of micturition, and rises of temperature, and following the last flare-up in April, 1934, the condition had become chronic. The urine was always turbid and contained large numbers of pus cells and *B. coli* and also some staphylococci. The cystitis persisted despite various forms of medical treatment.

On Dec. 3rd, 1934, he started taking mandelic acid (12 g. in die) and ammonium chloride, whilst carrying on his usual work. Ten days later the urine was much clearer and the growth markedly decreased, and after 17 days on the drug, the pathologist's report showed "few pus cells in the centrifuged deposit. Cultures give a very few colonies of *B. coli* and a few *Staph. albus.* This is the best specimen since the urinary condition started." The mandelic acid was stopped and three weeks later the urine was clear, with no deposit, a very few leucocytes were seen in the centrifuged deposit, and on culture it gave only a few colonies of *Staphylococcus albus* and no *B. coli.*

The patient was seen again nearly three months later. During that time he had had two slight relapses with frequency and bacilluria, but in each case three or four days' treatment with mandelic acid had caused a complete recovery and for the past month he has been symptom-free with no treatment. The last specimen of urine examined on March 20th was clear, contained no pus cells, and was sterile on culture.

CASE 2.—A man, aged 72, was admitted to Westminster Hospital under Dr. A. W. Stott in January, 1935, with auricular flutter and a chronic *B. coli* infection of his urinary tract.

He had previously been in hospital in November, 1933, when he was admitted for treatment of a chronic sinus following an ischiorectal abscess. While in hospital he developed a urinary infection and on examination was found to have an enlarged prostate and calculi in his bladder. He also had auricular flutter. Two stones were removed from his bladder and he passed a third shortly after discharge.

He attended the out-patient department regularly, and despite treatment with various drugs his urinary infection persisted. Though no stones were present in his bladder on his second admission, his urinary condition was unaltered. He had a number of prostatic calculi.

On Jan. 30th he started treatment with mandelic acid. His urine became highly acid and he complained of some burning pain on micturition. The urine became clearer and the number of *B. coli* fell, and on Feb. 6th culture showed only 5 colonies per drop. He was kept on the acid, but though he improved clinically, sleeping and feeling better, and though his urine became clear apart from a deposit of mucus, it always contained pus cells and it remained infected, growing between 30 and 90 colonies per drop. While on treatment he had some granular and hyaline casts in his urine, but these had been noted in his urine on a previous occasion. He always had a trace of albumin in his urine.

While his urinary infection was controlled, a further attempt to stop his auricular flutter with digitalis and quinidine was made but failed. On Feb. 28th the mandelic acid and ammonium chloride were stopped and he was placed on alkalis and free fluids. When he was discharged on Feb. 8th his urine was again turbid and contained large numbers of *B. coli.* He has recently started a second course of mandelic acid as an out-patient, and after one week's treatment there were again only 7 colonies per drop of urine on culture.

CASE 3.—A woman, aged 22, was admitted to University College Hospital under Prof. T. R. Elliott. For three weeks before admission she had had frequency of and pain on micturition. On admission she was found to have a *B. coli* cystitis and was treated with large doses of alkalis and was encouraged to drink as much as she could. She improved considerably, but her urine remained infected and she still had slight pain on micturition. On Jan. 29th her fluid intake was restricted and she was started on ammonium chloride 8 g. daily. On Feb. 1st, though feeling well, her urine was still infected and mandelic acid was started. A week later she felt perfectly well, was getting up, and had no nocturnal frequency. On Feb. 11th her urine contained a few epithelial cells, had a very faint trace of albumin, and showed no growth on culture. She was discharged, and 14 days later her urine was still sterile and she was feeling perfectly fit.

CASE 9.—A primipara, aged 25, four months pregnant, was admitted to University College Hospital under the obstetric unit on Nov. 5th, 1934, with pyelitis. She had had a dragging pain in her back, frequency, and scalding on micturition for some six months. She had been in hospital in 1931 and 1933 for treatment of a chronic *B. coli* cystitis and had had recurrent attacks of frequency and pain in her right side.

Her urine on admission was clear, an uncentrifuged drop showed numerous organisms while there were a few pus cells in the centrifuged deposit. On culture it grew *B. coli.* On Nov. 15th she was started on mandelic acid treatment, but her condition did not improve and the urine remained infected and became slightly more turbid. She was vomiting a lot, and on Dec. 3rd, following some slight uterine pains, the acid was stopped.

On Dec. 11th she was started on the ketogenic diet, but though her urine, with the aid of ammonium chloride, was kept acid, and though strongly positive Rothera and slightly positive ferric chloride reactions were obtained in her urine, she did not improve, and on discharge on Jan. 1st, 1935, her urine was still infected. She was afebrile throughout her stay in hospital and both the mandelic acid and the ketogenic diet appeared to be without effect on the infection. An intravenous pyelography showed no abnormality of her urinary tract.

CASE 11.—A primipara, aged 24, six and a half months pregnant, was transferred from another hospital to the obstetric unit at University College Hospital on March 1st, 1935. She had been treated for the past five weeks for pyelitis, complaining of pain in the back and loins, frequency of micturition, and shivering attacks. An intravenous pyelography done at the other hospital showed a well-marked hydronephrosis of both kidneys with a slight impairment of excretion in the five-minute film. No calculus was seen. She had been treated with large doses of potassium citrate, but though her general condition had improved the infection persisted.

On admission to University College Hospital she had no pyrexia, but her urine was still cloudy, contained a trace of albumin, and the uncentrifuged drop showed organisms and pus cells in plenty. On culture it grew *B. coli.* On March 6th her urine contained about 148,000,000 organisms per c.cm., and mandelic acid treatment was started. On March 9th she stated that she had felt better for the past two days, her back was not so bad, but she had some buzzing in her head. Her urine was clearer, showed only an occasional pus cell in the uncentrifuged drop, and on culture contained only 48 typical and some 800 atypical *B. coli* per c.cm. On March 13th she felt much better, had had no pain in the back for the past two days, and on culture of her urine no typical colonies of *B. coli* were seen. By March 16th, ten days after the treatment was started, she was up and walking about. She felt very well apart from a dragging sensation in her back when she was up (she had been in bed for seven weeks). Her urine was clear but contained a trace of albumin. No pus cells or organisms were seen in a centrifuged drop and there was no growth on culture. She was sent home and on April 3rd, without any further treatment (after March 18th), her urine was still sterile and she felt very fit.

(Her urine contained a trace of albumin on admission. During the first week of treatment this disappeared, but on getting up a trace of albumin rea[illegible] for a short time. It seems unlikely that the albuminuria was due to the mandelic acid.)

Conclusions

An attempt to discover a therapeutic agent that might replace the ketogenic diet in the treatment of urinary infections has led to the clinical trial of mandelic acid.

Mandelic acid appears to be effective in cases of urinary infection unassociated with urinary obstruction, and it is hoped that a more widespread trial of the acid may confirm the favourable impression gained from the present short series of cases.

It is a pleasure to acknowledge my indebtedness to Prof. C. R. Harington and to thank him for his invaluable help and advice throughout the course of this work. My thanks are also due to Miss G. H. Dodds of the obstetric unit, University College Hospital, to those physicians who have kindly permitted me to treat cases under their care, and to Prof. C. C. Okell, in whose laboratory the bacteriological investigation was carried out.

ONE HUNDRED CASES OF
CHRONIC ARTHRITIS TREATED BY GOLD

BY H. S. PEMBERTON, M.B. Liverp., M.R.C.P. Lond.,
PHYSICIAN TO THE DAVID LEWIS NORTHERN HOSPITAL, LIVERPOOL; LECTURER IN CLINICAL MEDICINE IN THE UNIVERSITY OF LIVERPOOL

IN their report[1] on the causation and treatment of arthritis and allied conditions, the British Medical Association committee say of the use of gold: "Gold preparations given by intramuscular injection have been used abroad for the treatment of arthritis, but beneficial results have not been confirmed." This statement probably has reference to the work of Umber's[2] clinic, where Solganal was used in 250 cases of infective polyarthritis; to Forestier's[3] first publication in THE LANCET, where he described the effects of Allochrysine in 48 cases of rheumatoid arthritis; to the work of Slot and others,[4] who have treated 14 cases of arthritis by solganal; and, finally, to another report by Forestier,[5] who records results in 500 cases of arthritis, using various preparations of gold. In all these communications good results and even cures are reported.

The present paper sets out the results of five years' work with three preparations of gold in the treatment of 100 cases of chronic arthritis. The actual number treated in this way is much larger, but complete records and the possibility of inspection were only available in something over 100 patients, the others being seen and dealt with as out-patients only.

THE INVESTIGATION

Selection of cases.—The term chronic arthritis is used in preference to anything more exact because, as Table II. shows, the types of joint lesion varied widely; but, so far as is known, no arthritis of specific ætiology is included—a matter of difficulty in some cases of Neisserian infection, where the resemblance to rheumatoid arthritis is often close. Otherwise no particular selection has been made, although the rheumatoid group tends to predominate; the aim being to test the effect of this treatment in as wide a range of arthritics as possible. Cases of spondylitis have not been included; nor has the sedimentation test, as suggested by Forestier, been always employed as a test of infection.

Preparations of gold used.—Three types of gold salts have been used, and most of the cases have had one course of six or more injections only, although a few have had a second or a third course at intervals of three months. In the earlier cases we used sodium aurothiopropanol sulphonate (Allochrysine: metallic gold, about 35 per cent.) in doses of 1·5 to 2·0 g., given either intramuscularly or intravenously in six doses, one a week. Later sodium gold thiosulphate (Crisalbine: metallic gold about 37 per cent.) was given in doses of 1·5 to 3·0 g. intravenously in six doses. Most recently sodium gold thiomalate (Myocrisine: metallic gold about 50 per cent.) has been employed. Up to 2·0 g. is given intramuscularly in oily suspension in graduated doses over a period of six weeks or more.

Toxicity.—There is no doubt that all these preparations of gold can give rise to toxic manifestations; and the recent observations of Holmes[6] is one with which most workers with gold will agree. From my own series I would say that whilst few patients escape without any toxic signs or symptoms, in the great majority they are slight; nor do they appear to do any better because they have been poisoned, although they like to think so. In order of frequency, I would rank these phenomena as follows:—

(1) Pyrexia and increased periarticular pain or swelling.

(2) Rashes of all kinds; macular and scarlatiniform being most common. One of my earliest cases with allochrysine was sent in good faith, as a case of measles, to a fever hospital—and accepted. All these rashes have the common features of marked irritation and desquamation, and are sometimes accompanied by so much œdema as to render the patient unrecognisable.

(3) Sore tongue, stomatitis, and diarrhœa.

(4) The appearance of what look and feel like chilblains in the fingers.

The dose or type of gold used does not seem to bear any relation to the toxic appearances, which come both early and late; some measure of control may, perhaps, be obtained by using Hepatex or Contramine, and lately I have been trying gold dissolved in calcium gluconate for intravenous use.

Arthritics who, on preliminary investigation, show albuminuria, raised blood-urea, poor clearances, or any evidence of liver defect, are not suitable for chrysotherapy; and in those who exhibit toxic features a halt should be called at once. A poor lævulose tolerance does not seem to be necessarily a contraindication, and even in cases to which gold has been mildly toxic I have gone on with the treatment without any increase in the poisoning as shown either by signs or biochemical estimations. On the other hand, emaciated arthritics of the depletive type often show a remarkable general, as opposed to an articular, response to gold; and I have been struck in not a few cases of this type by the increase in weight, well-being, and even number of red blood-cells which was shown—long before the arthritis appeared to be in any way affected.

Adjuvant treatment.—In many of the more chronic cases, all known types of treatment for arthritis had already been tried without success; and whilst, as Table II. shows, response to gold is roughly in inverse proportion to the duration of the lesion, a considerable number of these chronic cases exhibited in no uncertain manner the striking superiority of this to any previous method of therapy.

Along with gold, the following measures have usually been employed—so commonly and so much as a routine as to discount the probability of betterment being due to their agency alone. In the obese, the diet was reduced in calories and carbohydrate, the former roughly to 1000 calories per diem ; in the more usual type of rather under-weight patients, a full diet rich in vitamins A and D was given, but with carbohydrate-restriction in those showing a diminished glucose tolerance. If hydrochloric acid was absent from, or diminished in, the gastric juice 0·4 per cent. acid was given by mouth generously. When the course of gold has been completed, massage, diathermy, and both active and passive movements have usually been started ; whilst, finally, if effusions were large and recurrent, they have been aspirated, and, wherever possible, deformities such as obstinate knee flexion have been treated by firm splinting.

RESULTS

The results are shown in Tables I. and II. On examination the records in these 100 cases did not, I felt, warrant any further analyses beyond these : no particular relationships as to improvement or otherwise were found to exist ; for instance, in those cases which did or did not exhibit diminished glucose tolerance, achlorhydria, or focal sepsis. It is natural enough perhaps that no osteo-arthritics were cured, but the improvement that some of them showed was remarkable. Such factors as age, both of patient and disease, are inevitably to be related to the result and, in this series, the progressive resistance is even enough.

TABLE I

Years after gold treatment.	Total cases.	Cured.	Very much imp.	Imp.	I.S.Q.
5 years	3	1	1	—	1
4 ,, ...	18	3	3	4	8
3 ,, ...	18	2	9	5	2
2 and less ..	61	6	25	29	1

Cured, 12 per cent.; very much improved (imp.), 38 per cent ; improved, 38 per cent.; in statu quo (I.S.Q.) 12 per cent.

TABLE II

Analysis of cases.	Cured.	Very much imp.	Imp.	I.S.Q.
Average age at beginning of treatment	32	49	45	56
Number of men ..	6	5	14	9
,, women ..	6	33	24	3
Average duration of arthritis (years) ..	1·58	5	5·18	7
Clinical type of arthritis—				
Osteo-arthritis ..	—	4	9	4
Rheumatoid	12	27	22	8
Menopausal	—	5	7	—
Gold used—				
Allochrysine	4	6	4	7
Crisalbin	6	16	25	5
Myocrisine	2	16	9	—

The results have been classified as " cured," meaning that both symptoms and signs of disease have gone ; " very much improved," meaning that symptoms have gone although some signs remain ; " improved," meaning that both symptoms and signs remain, but to a lesser extent in one or the other or both ; and as those which remain in statu quo antequam. None appear to have been made worse.

SUMMARY

(1) 100 cases of chronic arthritis have been treated with three preparations of gold and watched over a number of years. (2) The preparations of gold have all proved to be toxic to some patients. (3) The adjuvant treatment has been standardised. (4) Twelve cases have been cured, 38 very much improved, and 38 improved. Twelve remain the same.

STUDY OF A CASE OF IDIOPATHIC HYPOPROTEINÆMIA

BY C. L. COPE, D.M. Oxon., M.R.C.P. Lond.
SENIOR BEIT MEMORIAL RESEARCH FELLOW ; AND
H. K. GOADBY, M.D. Camb., M.R.C.P. Lond.
DEPUTY DIRECTOR OF MEDICAL UNIT, ST. THOMAS'S HOSPITAL, LONDON

THE following case is reported because we believe it to be representative of an uncommon, but nevertheless definite clinical condition, the further study of which may throw some light on the site of formation of the blood proteins.

THE CASE AND ITS INVESTIGATIONS

The patient, aged 20, employed as an engineer's apprentice, was admitted to St. Thomas's Hospital in May, 1934, complaining of swelling of his face and ankles of about six months' duration.

This swelling had come on insidiously, reaching its maximum in about a month and varying somewhat in intensity subsequently. On rising in the morning it was most marked in the face, particularly the eyelids, which could sometimes scarcely be opened. During the day this subsided, to give place in the evening to considerable swelling of the feet, ankles, and shins.

Apart from occasional nocturia, present since childhood, there were no other symptoms. His general health and activity were unimpaired, and the exercise tolerance was good. Diet and appetite were entirely normal and there was no history of digestive disturbance. He had had scarlet fever 11 years previously without complications. There was no family history of a like condition, nor of cardiovascular or renal disease.

On admission he was found to be rather pale, but of normal muscular and skeletal development. There was generalised pitting œdema of the lower limbs extending up to the dorso-lumbar region. No other abnormal physical signs were discovered. Blood pressure was 94–110 mm. Hg systolic and 64–70 mm. diastolic. The urine on repeated examination never contained any albumin, red cells, or casts. The blood contained 5·6 million red cells per c.mm., with 107 per cent. hæmoglobin. The differential white count was normal, but with a total of 10,500 cells per c.mm. The teeth and tonsils were perfectly healthy. The Wassermann reaction was negative. The optic fundi were normal. The sella turcica as seen by radiography appeared of normal size and shape.

Tests for renal function gave the following figures which could not be considered to fall outside the normal limits of variation : A maximum urea clearance of 70 per cent. of the average normal figure, a creatinine clearance of 125 c.cm. per minute, and the elimination of 860 c.cm. of urine in the four hours following the ingestion of a litre of water, the specific gravity falling to 1003.

The resting gastric juice contained 0·2 per cent. of free HCl and 0·042 per cent. of combined, a total of HCl of 0·24 per cent. which rose to 0·30 half an hour after 0·5 mg. of histamine.

During his stay in hospital the intensity of the œdema varied spontaneously and considerably, his body-weight swinging between 10 and 11 st., often varying 4 or 5 lb. n the course of a few days without obvious cause.

The picture is one of a youth of good general health and physique, suffering from a generalised œdema due to none of the more usual causes of this condition. There was no evidence of renal damage, cardiac failure, undernutrition, or anæmia. The immediate exciting cause of the œdema was, however, found in the plasma protein concentration, the following low figures being obtained :—

Total protein	4·64 g. per 100 c.cm.	(6·4 to 8·0)
Albumin	3·13 ,, ,,	(3·8 to 5·2)
Globulin	1·51 ,, ,,	(2·2 to 3·5)
Albumin-globulin ratio	2·1 ,, ,,	(1·4 to 2·2)

(The figures in parentheses are the normal limits of variation for each fraction.)

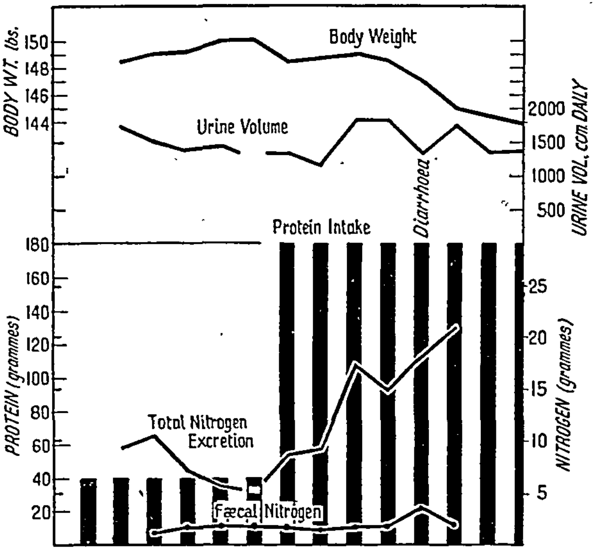
It is in the lack of any demonstrable cause for this low plasma protein concentration that we consider the interest of the case lies. Such a low protein concentration must presumably be due either to excessive loss of protein from the blood stream, to inadequate formation, or possibly to an abnormal setting of the mechanism regulating blood concentration. There was no evidence of excessive loss in this case. Moreover, in cases of hypoproteinæmia due to protein loss, the reduction usually occurs mainly, and often entirely, in the albumin fraction, producing a reduction in the albumin-globulin ratio. In the present case, however, both fractions are equally reduced, the albumin-globulin ratio remaining within normal limits. The possibility that unduly rapid breakdown of plasma proteins was occurring could not be excluded, but was considered to be improbable. It had to be concluded therefore that the primary fault lay in an inadequate formation of these proteins, either because of a deficiency of one of the substances necessary for their formation or because of some abnormality in the mechanism controlling their concentration.

That such causes of low plasma protein concentrations do exist is now recognised, but they are apparently very rarely encountered in such an uncomplicated form. In the œdematous types of nephritis, for instance, loss of protein in the urine is frequently inadequate to account for the low protein concentrations in the plasma, the conclusion appearing inevitable that in such cases plasma protein formation is impaired. The hypoproteinæmia found in conditions of malnutrition, especially when protein intake is low, and in severe wasting diseases, is also referable presumably to inadequate formation, but such possible causes were not recognisable in the present case.

That there was no lack of ability to absorb food protein normally from the alimentary canal was indicated by the following experiment (see Figure).

The patient was kept in bed, and was put on a diet containing only 40 g. of protein and 4·6 g. of salt and having a calorie value of 2500. At the end of six days the protein content of the diet was increased to 178·5 g., the calorie value and chloride content remaining as before. This diet was continued for a further period of six days. During the whole of this 12-day experiment the stools were collected daily and analysed for total nitrogen, and the mixed daily urine excreted was analysed for total nitrogen, creatinine, urea, uric acid, chlorides, the inorganic, ethereal and neutral sulphates, and occasionally for phenols and amino-acids. The curves of excretion of all these substances were quite normal and are therefore not shown here. The nitrogen content of the stools remained at about 1·7 g. per day, being quite independent of the amount of protein in the diet. On one day when the giving of a purgative evoked a diarrhœa a temporary increase was recorded.

Thus no abnormal amount of protein was being lost in the stools. There was on the low protein diet a small negative balance of protein, and on the high a considerable positive retention of nitrogen, but in spite of this there was no significant change in the plasma protein concentration. Body-weight rose slightly on the low protein diet, to fall once again on the high, but the change was scarcely large enough to be significant, and the fall was not maintained. The experiment provides evidence that protein storage readily took place, and that in its gross aspects at least the metabolism of exogenous protein was not abnormal.



Daily nitrogen excretion on low and high protein intakes.

Further evidence of the normal exogenous protein metabolism is provided by an observation made on the day of transition from a low to a high protein diet. On this day the opportunity was taken to determine the specific dynamic action of protein on the metabolic rate. The data obtained were regarded as quite normal, and as further contributory evidence that the intermediate metabolism of exogenous protein was not seriously disturbed.

8.40 A.M.	Resting metabolic rate ..	28·7 cal/sq.m/hour.
9.25 A.M.	,, ,, ,, ..	30·2 ,, ,,
10.0 A.M.	Meal containing 170 g. of mixed protein.	
1.0 P.M.	Resting metabolic rate ..	35·2 cal/sq.m/hour.
2.45 P.M.	,, ,, ,, ..	35·6 ,, ,,

There was thus no reason to suppose that the body was suffering from an inadequate supply of protein metabolites, and this view was further strengthened by the fact that whilst in hospital and again after leaving, the patient was for several weeks on a diet containing large amounts of protein (meat or liver) without this causing any alleviation of the œdema or rise in the plasma protein concentration (see Table).

Date in 1934 ..	June 8	18	24	Aug. 4	Sept. 17
Diet	Low protein.	High protein.	Whole liver.	Normal	Normal
Total protein (g. %)	4·58	4·56	4·26	3·70	4·10
Albumin (g. %) ..	2·90	2·67	2·76	1·94	2·50
Globulin (g. %) ..	1·69	1·89	1·51	1·77	1·64
Alb.-glob. ratio ..	1·71	1·41	1·83	1·09	1·52
Fibrinogen (g. %) ..	0·45	0·80	0·66	—	—
Non-protein nitrogen	23·0	40·0	44·0	37·0	35·0
Urea	25·0	56·0	—	—	—
Uric acid	3·0	2·7	3·3	—	—
Calcium	10·1	8·8	8·9	—	—
Phosphorus ..	4·1	5·0	3·5	—	—

It appeared necessary to conclude therefore that the fault lay in those tissues responsible for the formation of the plasma proteins or for the regulation of their concentration.

Because of our almost complete lack of knowledge of the site and mode of action of these tissues, it was not easy to proceed further with the investigation of this case. Several possible sites of formation have been suggested. Among these are the liver, the bone-marrow, the reticulo-endothelial system, and the intestinal mucosa.

Clinically there was no reason to suspect the liver. The fibrinogen fraction of the plasma protein, for the hepatic origin of which there is considerable evidence, was above rather than below the normal. And a lævulose-tolerance test showed a rise of blood-sugar of less than 20 mg. after 50 g. of lævulose.

No biopsy was performed, so that the state of the bone-marrow is not known; but radiograms furnished no evidence of any lesion involving the marrow, and the normal blood count indicated a normally functioning hæmopoietic system. The condition of the intestinal mucosa and of the reticulo-endothelial system could not be investigated.

DISCUSSION

From the investigations which have been carried out we draw the conclusion that the hypoproteinæmia present in this case, and presumably responsible for the œdema, is not due to any of the generally recognised causes of this condition, but is due solely to a deficient production of the plasma proteins. It seems justifiable to describe the condition as one of idiopathic hypoproteinæmia.

Christian, in a recent review of the causes of œdema, mentions deficient plasma protein formation as a possible cause, but makes no reference to definite cases of the condition, except in malnutrition or occasionally from myelomatous involvement of the bone-marrow.

We have been able to find on record only one other clear case of this idiopathic condition. This was reported in 1933 by Myers and Taylor of Boston. The description of their patient, an Irishman of 51 years, agrees in all essential features with that of our own. The plasma proteins were persistently low, usually below 4·0 per cent., the deficiency affecting almost equally the globulin and albumin fractions. There was the same lack of abnormal clinical findings, of evidence of abnormal protein metabolism, and of response to treatment by high protein diet or in other ways.

Another case of apparently similar type, but complicated by Graves's disease and persistent diarrhœa, has been reported by Mussio-Fournier, *Castiglioni, and Anido*. This was a woman of 38, with extensive œdema and a total plasma protein of 4·27 per 100 c.cm., with an albumin-globulin ratio of 2·3. But it seems possible that in this case enteritis was an ætiological factor, although the authors state that no cause was found for the low plasma proteins and œdema.

A few other cases which may possibly be of the same type have been reported in Germany. In 1922 Jungmann described a man of 28, suffering from weakness and œdema, with plasma proteins varying between 3·9 and 5·0 per cent., no cause being discovered for the low values. Meyer-Bisch also, in 1925, reported having seen three cases of œdema without albuminuria or anæmia, but with low plasma proteins, in one case only 3·4 per cent.

Common to the cases of Meyer-Bisch, of Mussio-Fournier, and of Jungmann was an achlorhydria gastrica. Myers and Taylor also reported absence of free acid from the resting juice in their case, although after histamine the acid content was normal. In our own case the gastric acidity was not abnormal. But in view of the evidence suggestive of association of idiopathic hypoproteinæmia with abnormal gastric function, an attempt was made to improve the condition of our patient with doses of Pepsac, in the hope that it would yield in a way analogous to that of pernicious anæmia. No success was obtained, the hypoproteinæmia remaining as unresponsive to this as to the high protein and whole liver régimes.

We consider it probable, however, that in such cases as this there is lacking one of the factors responsible for the formation of plasma proteins or for the control of their concentration, and it is for this reason that we believe the case to be of interest, for such a condition is seldom encountered in such an apparently uncomplicated form.

SUMMARY

A case is described of generalised œdema in an otherwise healthy man, due to low plasma protein concentration for which no cause has been found. Other apparently similar cases have been collected from the literature.

ADDENDUM

When last seen on April 10th, 1935, this youth was *still at work, but still had his œdema and hypo*proteinæmia with 4·4 per cent. total protein and albumin-globulin ratio of 1·38.

TECHNIQUE OF EVIPAN ANÆSTHESIA

BY A. DICKSON WRIGHT, M.S. Lond., F.R.C.S. Eng.
SURGEON TO OUT-PATIENTS, ST. MARY'S HOSPITAL, LONDON

THE value of Evipan as an anæsthetic is now well established, and it is in constant use in many hospitals. Some surgeons have enlarged its scope to include almost every surgical operation except prolonged intracranial procedures, while others use it for minor operations only. In dentistry it is now a well-tried and satisfactory anæsthetic. I have also found in spinal anæsthesia that the vomiting and restlessness which disturb in upper abdominal operations cease with 2–3 c.cm. of intravenous evipan.

The anæsthesia is, however, often marred by faulty intravenous technique. I have often seen numerous punctures made owing to the vein not being found, or the needle slipping out either from the patient's movements or inattention on the part of the injector. The result is that at the end of the operation there is much hæmatoma in front of the elbow and some evipan in the tissues, and the patient complains of pain in this region afterwards. More important still, the cubital veins may all be used up and obscured by hæmatoma and the surgeon asking for a little more anæsthesia at the end of the operation which the anæsthetist is not able to give. It is possible, too, that the normal work of the anæsthetist does not include much intravenous work, and they have not the facility in this direction which comes from constant practice. It is in order to eliminate all the risks of failure that I put forward the following details of technique which, if followed, will make for the smooth working so necessary in any new method of anæsthesia.

The arm is first of all fixed upon the aluminium splint shown in Fig. 1. The splint was made to my design by Down Bros., it is padded with Dunlopillo, and the upper strap is a pneumatic armlet with a simple stud system of fixing instead of the rather troublesome method employed in most blood-pressure machines. The armlet is inflated at once before mixing the evipan solution, so as to give the veins time to swell before injecting. If a difficult injection is anticipated because of fat or other cause, then a hot-water bottle is laid over the front of the elbow to increase the dilatation of the veins and the patient is instructed to clench the fist rhythmically. The skin is painted with spirit, not iodine, as this latter might rob one of the help that the blue line of the vein gives in some cases.

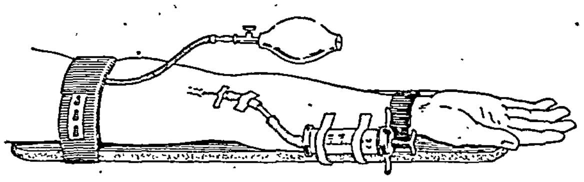

FIG. 1.—Method of fixing arm for simple evipan injection.

The evipan syringe is of 10 c.cm. capacity except when a prolonged anæsthesia is expected, when a 20 c.cm. syringe is used. The needle is connected to the syringe by six inches of thin rubber tubing, and it is a good plan to have a small glass tube included in this to see the blood flow, but this is by no means necessary as the sensation of going into a vein with a sharp needle is unmistakable. As soon as the needle is in the vein the armlet is deflated and the injection commenced. When the first cubic centimetre has been introduced without causing any pain or bleb at the point of the needle, the latter is fixed to the skin by two small strips of adhesive, and the syringe is laid in the groove between the splint and the arm and fixed with a strip of adhesive in such a way that the calibrations can be seen easily. Now with the patient's arm immobilised and the needle independent of the syringe no fear of dislodgment need cause worry. A nurse can be deputed to hold the arm and inject a cubic centimetre as requested by the anæsthetist, who sits by the patient's head while induction is in progress.

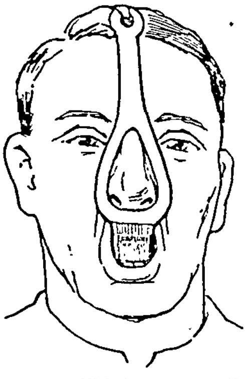

FIG. 2—This type of mouth prop presses the lower incisors forward.

The maintenance of the airways in the anæsthetised patient is best ensured by the type of support shown in Fig. 2, which is very practical and reliable and absolutely prevents the jaw from falling backwards. The usual short aluminium airway put between the teeth does not prevent this, and after all it is surely better for the patient to breathe through his nose even while under anæsthesia. Moreover, the pushing of the angles of the jaw forward is often done with unwarranted force, and there is some reason for regarding this trauma as the cause of post-operative parotitis.

For long operations under evipan anæsthesia I have used the following method (Fig. 3). The arm is fixed in the splint as before, and an intravenous drip saline is given into one of the cubital veins. The indiarubber tubing, 6 inches from the intravenous needle, is punctured by the evipan needle, and this time the syringe is directly connected with the needle and laid in the groove beside the arm as before. The evipan can now be injected directly into the intravenous stream as desired, and a sustained anæsthesia kept up for any length of time; for instance, in a recent case of laminectomy for 2½ hours (27 c.cm. of 10 per cent. evipan). Should the patient require the constant intravenous drip after the operation for shock, uræmia, or other cause, then the arm can be left on the splint, and any restoratives or sedatives can be injected by puncturing the intravenous rubber tube.

The intravenous splint is also of great value in uroselectan injections, blood transfusions (donor and recipient), novarsenobenzol injections, and all forms of intravenous treatment.

There is no detail of the technique so important as the sharpening of the needle which is done as shown in Fig. 4.

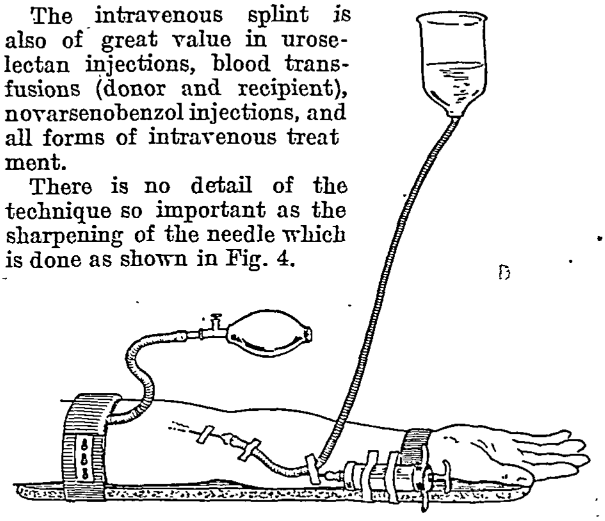

FIG. 3.—Method for prolonged administrations. A sight drip should be inserted in the tube leading from the reservoir.

The needle is inserted obliquely through a cork so that the bevel appears on the rounded surface of the cork. Then a special needle hone of Arkansas stone is drawn lightly across the bevel till the whole ring of the bevel glistens. Then the needle is pushed further through the cork, and the edges lightly stroked with the needle stone to remove any feathering of the edges which may be present. Finally, the needle is removed from the cork and drawn lightly over the finger to be sure that there is no "crochet hook" at the tip of the needle, and if this is present, it is smoothed off with the stone. With such treatment a perfect point is assured and this makes injection infinitely easier.

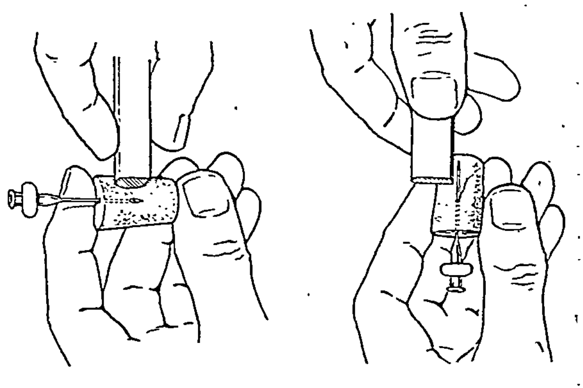

FIG. 4—Method of sharpening needle by hone.

If the usual needle taken at random in the theatre or ward is inspected with a magnifying glass and compared with a sharpened needle the necessity for honing the needle is made very clear.

MANCHESTER AND SALFORD HOSPITAL SATURDAY FUND.—An increase in income of £14,000 is reported by this fund, which has raised £601,313 in 28 years.

CLINICAL AND LABORATORY NOTES

FATAL ENTERITIS DUE TO SALMONELLA ORANIENBURG

By J. C. Kerrin, M.D. Aberd., D.P.H.
ASSISTANT DIRECTOR OF THE PUBLIC HEALTH LABORATORY, UNIVERSITY OF MANCHESTER; AND

A. T. Elder, M.B. Glasg., B.Hy., D.P.H.
ASSISTANT SUPERINTENDENT, FLORENCE NIGHTINGALE HOSPITAL, BURY

With a note by

J. Smith, M.D. Aberd., D.Sc.
BACTERIOLOGIST TO THE CITY HOSPITAL, ABERDEEN

Cases of food poisoning in this country are due usually to *Salmonella typhimurium* (*Bacillus aertrycke*); thus in a recent paper Smith[1] mentions that of 60 outbreaks in the north-east of Scotland it was responsible for 35. Less often the condition is caused by *B. enteritidis*, while from time to time sporadic cases occur in which the infective agent is a rarer member of the group. With many of the types, infection in this country has not so far been reported, and it is thought that the following case of fatal enteritis which occurred in Bury and which was traced to the Oranienburg strain of salmonella (Kauffmann[2,3]) is worthy of record, since hitherto this organism has not been met with in Great Britain. The case was sporadic and the source of infection is unknown.

Mrs. A. was admitted to the Florence Nightingale Hospital, Bury, on Oct. 27th, 1934, as a suspected case of typhoid fever. The illness commenced on Oct. 2nd with shivering, vomiting, and headache;, at first there was no abdominal pain or tenderness, but slight tenderness developed during the second week of illness. The Widal reaction on Oct. 25th was as follows:—

B. typhosus	(H)	.. nil	*S. paratyph.* B (O)	.. nil
,, ,,	(O)	.. nil	*Br. abortus* ..	.. nil
S. paratyph. A	(H)	.. nil	*Salmonella group*	.. 1/160
,, ,, B	(H)	.. nil	*Culture of clot* ..	negative

Diarrhœa had begun the day before taking of the blood sample, three weeks after the onset of the illness.

On admission to hospital the temperature was 100° F. and the pulse-rate 104. General condition was fair: tongue thickly coated, reddened throat, small tonsils, and the soft palate and fauces covered with sticky mucus. Heart and lungs normal; slight cough. Nervous system normal. No abdominal distension. Slight tenderness over splenic area but no enlargement of the spleen could be detected. Nil abnormal in urine, stools three or four per day, pea-soup in appearance.

The temperature fell gradually to 97° F. and the pulse-rate to 84. Cough became gradually worse and the sputum was thick and tenacious, looking somewhat like broken-down lung tissue. No tubercle bacilli were found, and while in film numerous pneumococci were present, no cultures were made. The patient's general state gradually grew worse with general loss of flesh.

On Nov. 15th there was a sudden rise of temperature to 102·6° F. with a pulse-rate of 124. The patient vomited and became dyspnœic, complaining of abdominal discomfort, but no great pain or tenderness in the abdomen was noted. On Nov. 17th the temperature had once more fallen to 97° F. Weakness was very marked and death occurred on the 21st.

Post-mortem findings.—Heart: small, muscle very flabby; no valvular or arterial disease. Lungs: hypostatic congestion of base of right lung; no evidence of tuberculosis or new growth. Liver: large and pale; gall-bladder very distended and full of bile; no gall-stones. Kidneys: normal. Suprarenals: normal. Intestines: small intestine showed patches, a foot and more in length, of inflammation and minute hæmorrhages, especially in the ileum.

Bacteriology.—Specimens of blood and fæces were again received at the laboratory on Nov. 2nd. The Widal reaction was now completely negative, no agglutination of the group salmonella being detected. The blood clot was incubated in 0·5 per cent. sodium taurocholate, and after three days' incubation growth was obtained of a salmonella organism similar to that isolated from the fæces. Direct plating of the fæces gave negative results, but from growth in 1/200,000 brilliant-green broth a pure culture of a salmonella was obtained. The organisms isolated gave the general characters of the group, being actively mobile and fermenting (with the production of acid and gas), glucose, mannite, dulcite, maltose, xylose and arabinose. Lactose, saccharose, and inosite were not fermented. Hydrogen sulphide was produced, and after a preliminary acidity in litmus milk the reaction became markedly alkaline. Indol was not formed. No agglutination was obtained with the following H sera: *S. paratyphosus* B, *S. typhimurium*, the Newport strain, *S. enteritidis*, *S. suipestifer* (European), and *S. paratyphosus* C, and the organism was submitted to Dr. Smith for typing, who reported it as *S. oranienburg*.

At the post-mortem examination a specimen of bile and a portion of the ileum were taken for examination and from both of them this organism was isolated in pure culture. On section of the ileum the mucosa showed necrosis, the blood-vessels of the submucosa were congested, and small groups of mononuclear cells were present in the submucous and muscular coats.

NOTE BY DR. SMITH

The serological examination of the strain showed that it agglutinated with the O serum for the paratyphoid C sub-group of the salmonella genus to a titre of 1/1600, and failed to agglutinate with any of the other O sera. An absorption test showed that it could completely remove the agglutinins from this serum. When tested against the H sera of the sub-group, it was agglutinated by the serum for the Oranienburg strain only, and that to full titre 1/25,000. Again, an absorption test showed that it could remove all the agglutinins. The antigenic structure of the organism is therefore represented by the formula VI, VII: mt., which corresponds to that of *S. oranienburg*.

CRURAL PARESIS ACCOMPANYING HERPES ZOSTER

By G. P. Chandler, M.D. Camb., M.R.C.P. Lond.

A crural paresis associated with an attack of herpes zoster appears to be a rare event. Worster-Drought and McMenemy[1] were only able to find records of two cases in their review of the subject. But recent researches in France by Lhermitte and Nicolas,[2] Lhermitte and Vermès,[3] and Faure Beaulieu and Lhermitte[4] suggest that some paralysis may occasionally be expected to accompany this disease.

These workers have shown that the morbid process in herpes zoster is much less localised than is often thought. There is an inflammatory reaction extending from the posterior root ganglion, involving the posterior root, the surrounding meninges, and the grey matter of the posterior horn, spreading in some cases to the pars intermedia and anterior horn of grey matter and passing up and down the cord for a variable distance. The microscopic changes consist of degeneration and vacuolation of the affected nerve-cells, with lymphocytic infiltration, vascular dilatation and hæmorrhage, the vascular changes being most conspicuous in elderly patients with poor arteries. The meninges show vascular dilatation and there is hyperplasia of the capsule of the affected posterior root ganglion. Shrinkage of the grey matter of the posterior horn may be obvious to the naked eye.

This conception of the pathology of the disease as a myelitis rather than a local inflammation in the posterior root ganglion suggests that a varying degree of paralysis may be not uncommon during an attack of herpes zoster. The occurrence of ocular palsies associated with herpes ophthalmica is not very rare. Other types of paralysis affecting the face, neck, arm, or abdominal muscles have been recorded by Hunt,[5] Masten,[6] Worster-Drought,[7] and others.

DESCRIPTION OF CASE

The patient was a gardener aged 60. He had always enjoyed good health, except for occasional colds and an attack of sciatica in the right leg twenty years ago. He was seen on Oct. 25th, 1934, with a two days' history of severe pain in the right leg. The pain was continuous but varied in intensity and appeared to be worse at night. It was described as being of a boring or gripping character unaltered by movement or rest. There was no disturbance of micturition or defæcation.

On examination he was a thin wiry man with dilated venules on the face. Temp. 98·6° F. (A.M.); pulse-rate 68. Heart not enlarged, sounds distant, arteries hard and rather tortuous. Blood pressure 160/90. The lungs, abdomen, and urine were all normal. All the cranial nerves and the fundus oculi were normal. There was slight weakness of the right triceps muscle. The abdominal reflexes were present. The right leg showed absent knee- and ankle-jerks and the plantar reflex was flexor. There was diminished power in the quadriceps, hamstrings, and calf muscles, but no obvious wasting. There was diminished sensation to pin-prick and cotton-wool on the anterior and outer part of the leg from the knee to the middle of the calf, and diminished vibration sense in the right tibia. Joint sense was normal. The left leg showed no abnormality. Romberg's sign was not present. The Wassermann reaction was negative.

Two days later a herpetic rash appeared on the anterior aspect of the right knee and on the anterior and outer aspect of the upper third of the leg below the knee. The rash pursued its usual course leaving a slight scarring. By Nov. 12th the pain in the leg was much less severe, and the rash was drying up. The patient complained of weakness in the right leg and a tendency for the right knee to give way under him when he got out of bed. There was considerable weakness of the right quadriceps and hamstring muscles and some wasting of the thigh. The right ankle-jerk was just present, the knee-jerk was still absent. No alteration in the other reflexes or in the area of analgesia.

On Dec. 12th the patient said he had returned to light work two days ago. He said that the right leg was still distinctly weaker than the left, but he was able to get around the garden. He still complained of a dull aching pain in his thigh. The power in the quadriceps and hamstring muscles of the right leg had much improved. The ankle-jerk was present but sluggish, the knee-jerk was still absent. There was no alteration in the area of analgesia. Examination of the cerebro-spinal fluid showed a trace of globulin and 0·025 per cent. of albumin. The fluid was clear in appearance and under normal pressure. The Wassermann reaction was negative.

On Jan. 25th, 1935, the patient felt well, he had lost his pain, and could walk and do his work almost as well as formerly, but the right leg still felt weaker than the left. Sluggish knee- and ankle-jerks on the right side were both obtained on reinforcement. There was still some weakness of the right hamstrings and the area of analgesia was present but less marked. Vibration sense in the right tibia was absent. On March 2nd the condition appeared to be unaltered.

DISCUSSION

In this case the eruption occurred in part of the distribution of the posterior root of the fifth lumbar nerve; it was accompanied by signs of involvement of the motor-roots of the fourth and fifth lumbar and first sacral nerves. The inflammatory reaction appears to have been of considerable extent in the region of the anterior horn, but localised in the posterior horn to the fifth lumbar segment and affecting the posterior columns to a slight extent.

If the modern view of the pathology of herpes zoster is correct and a myelitis of varying extent exists in every case, it seems probable that some degree of paresis of muscles supplied by the affected segment may occur more frequently than is generally thought, and that occasionally the major damage caused by the inflammatory reaction may fall on the anterior horn cells causing a lower motor neuron paresis affecting muscles supplied by one or more segments of the cord. This may accompany a localised herpetic rash, as in this case.

PUNCTURE OF INTERNAL JUGULAR VEIN DURING PHRENIC EVULSION *

By R. Atkinson Stoney, F.R.C.S. Irel.
VISITING SURGEON, ROYAL CITY OF DUBLIN HOSPITAL

The patient was a young man with disease of the right apex and cavitation. A previous attempt at artificial pneumothorax had proved unsuccessful owing to the presence of adhesions. It was decided therefore to perform a right phrenic evulsion under a local anæsthetic, and this was done on March 14th, 1935.

After infiltration with 1·0 per cent. novocain and adrenaline a 2½ in. vertical incision was made along the posterior border of the sternomastoid. All went well, the landmarks being duly defined, till the deep fascia covering the scalenus anticus was reached. In order to expose this more clearly, the assistant, who was standing on the opposite side of the table, was told to retract the sternomastoid. This he did with the blunt hook which he had been given to retract the omohyoid, instead of the broad bladed retractor usually used for the sternomastoid, and there was an immediate gush of dark blood filling the wound. The blunt hook had perforated and torn the internal jugular vein.

The hæmorrhage was at once checked by pressing the vein forward against the sternomastoid, but an attempt to catch the torn point in a pressure forceps only led to further tearing of the vein and more copious bleeding. After some manœuvring and blunt dissection, while the fingers still compressed the vein, two large clips were placed well above and below the tear, including some of the sternomastoid muscles as well as the vein in their grasp; they were closed, but not tightly. On removing the fingers from the torn vein the hæmorrhage was found to be controlled. It was then comparatively easy to free the vein sufficiently to pass an aneurysm needle round it. This was threaded with catgut and withdrawn; the catgut loop was divided, one piece being drawn upwards above the tear and the other downwards below it, and

---

* Based on a communication to the section of surgery of the Royal Academy of Medicine in Ireland on March 29th.

both were tied, completely occluding the internal jugular vein above and below the injury. The operation of evulsion was then proceeded with and the wound closed with deep catgut sutures and Michel's clips. The patient fortunately was unaware that there had been any serious accident. Healing was normal and convalescence was uneventful.

Thinking over the case it is easy to see how such an accident occurred, as the assistant from his position was unable to see the internal jugular vein covered as it was by the sternomastoid, though to the operator it was a very prominent feature of the landscape. For safety's sake no hook retractors should be used, only broad ones, and in future operations this practice will be followed. By good fortune a colleague was present in the theatre at the time of the accident and rendered timely assistance both moral and physical.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTIONS OF EPIDEMIOLOGY AND CHILDREN'S DISEASES

A MEETING of these sections to which members of the Society of Medical Officers of Health were invited, took place on April 26th, with Dr. J. D. ROLLESTON in the chair. The subject discussed was the problems of

Prophylaxis in Pulmonary Tuberculosis

Dr. ARTHUR MACNALTY said that the first step in the prevention of tuberculosis consisted in a recognition of the fact that it was an infective disease. It was formerly a fatal and widespread malady affecting all classes of society. Koch's discovery of the bacillus in 1882 established the disease as an infectious one, and opened the doors to organised research. A notable advance in the production of immunity was made by Calmette and Guérin when they produced the B C G vaccine, though the immunity produced by it was admittedly transient. The human type of the tubercle bacillus was the cause of nearly all cases of pulmonary tuberculosis, while Stanley Griffith's figures gave 5 per cent. of human tuberculosis as of the bovine type. It was recently shown that bovine pulmonary tuberculosis exists in both Scotland and England. The bovine type of bacillus conveyed in milk was mainly responsible for the infection of man through the alimentary tract.

The prevention of bovine tuberculosis could be considered from two standpoints. The first was the control and possible eradication of tuberculosis in herds of cattle, especially dairy cattle. It had been estimated that not less than 40 per cent. of the cows supplying milk in England were infected with tuberculosis, and probably from 1 per cent. to 2 per cent. of them actually yielded tuberculous milk. The second heading was the prevention of the spread of the disease to human beings. Under the first heading much had been done in recent years by tuberculin testing of herds. The Tuberculin committee of the Medical Research Council had devised the double intradermal test, and this had been made compulsory for the testing of certified herds, and had passed into almost universal use. J. B. Buxton and S. Griffith were now investigating, at Cambridge, the efficacy of immunisation of calves by B C G (Calmette's attenuated living vaccine) and other antigens. As to the second category of prevention, the diminution in non-pulmonary tuberculosis was encouraging. In 1919 the deaths from the non-pulmonary form were 10,328, and in 1933 the figure had fallen to 5405. Dr. MacNalty suggested that a part of this improvement was due to a safer milk-supply.

During recent years in the campaign against tuberculosis the State had come to realise that it was not merely a medical disease—one which concerned only the patient and as such received due attention in the consulting-room of the pulmonary specialist. Many factors favoured the spread of the disease, such as occupation, malnutrition, poverty, overcrowding, bad sanitary environment, *contact infection*, and the influence of other diseases. Its social implications were also appreciated. Antituberculosis work was now looked upon as an integral part of preventive medicine. It was important to find not only the early case but also the primary infecting case in a household. Examination of contacts needed greater attention. Often it was not the practitioner's fault if a case were not diagnosed until it was advanced, for, as has been said, "the working man cannot afford to be an early case of tuberculosis." There was still need for the public to be taught the wisdom of seeking advice at early stages of the disease; the Public Health Act, 1925, extended the power of local authorities to educate the public on these matters. The national tuberculosis scheme depended largely on the coöperation of the general practitioner, the first line of defence in prevention. Dr. MacNalty referred to the value of collapse therapy in its various forms and sanocrysin in treatment. The after-care of cases was still a difficulty, but it had been met by Sir Pendrill Varrier-Jones in his pioneer work at Papworth, and by other village settlements for suitable patients. The *mortality from tuberculosis had declined* by 72 per cent. in England and Wales since the 1851–60 decennium, but there still remained much to learn about the prevention of the disease.

MORBID ANATOMY

Dr. CHARLES MILLER dealt with the morbid anatomy of tuberculosis in children. He said he had been collecting and examining post-mortem material from cases of tuberculosis up to the ninth year of age since 1909, and he gave a summary of his findings. The total number of subjects examined was 5259. Of these, 419 were either full-term still-born infants, or did not live longer than 24 hours. Among those 419 there were no instances of tuberculosis. Among the 4840 children who survived 24 hours there were 940 cases of tuberculosis, or 17·8 per cent. Of the 940, 677 were cases of undoubted respiratory infections, as also were probably 14 cases of double infection. 218 cases were alimentary infections, and 21 were primary infections of the common respiratory-alimentary tract (the region between the lips and the epiglottis).

Respiratory infections had been found to be more *active, more progressive and more lethal than alimentary* infections; also these were more likely to cause hæmatogenous dissemination than those of the intestinal tract. No proof was available that human tubercle bacilli were more virulent than bovine; that respiratory invasions were more serious than intestinal ones might be due to anatomical differences and peculiarities. The prevalence of tuberculosis, irrespective of the special path of infection, increased in the first five years of life, after which age it remained fairly constant. Not all caseous and calcareous lesions could be regarded as inactive, though perhaps fibrous lesions could. The importance of the invasion of lymphatic tissue was very great, and in children glandular involvement was nearly always a prominent feature. In fatal cases in children it was difficult to say whether tuberculosis was the chief or only a remote cause of death. Among children in the first year of life the case-mortality-rate from tuberculosis was 81·4 per cent., whereas in the tenth year it was 34·8 per cent. Hæmatogenous dissemination, both general and partial, was most common in respiratory infections, and rarest in alimentary infections.

PREVENTIVE MEASURES

Dr. D. A. Powell said that, for all practical purposes, every case of pulmonary tuberculosis could be regarded as having been derived from some other person, and hence the supreme importance of taking every means of reducing the total amount of tuberculous inoculum at large. These measures he classified as follows: (1) the diagnosis and treatment of cases of pulmonary tuberculosis while still in the closed stage; (2) the search for occult cases; (3) the conversion of known open cases into closed cases by means of treatment, either directly by collapse methods, or indirectly by general sanatorium methods; (4) personal precautions taken by the patient against transfer of his infection to others; (5) measures to disinfect clothing and belongings at home, and the patient's isolation, the latter including segregation in an institution. He considered that segregation was the most logical and expeditious method of attaining the object of limiting the spread of tubercle. Sufficient beds should be available for every patient willing to remain in an institution until he became non-infectious. Patients should be taught the great importance of the means they were able themselves to undertake, and they should be made to understand that chemical disinfection was not so valuable as thorough and regular soap-and-water cleanliness. Until it was possible to sterilise articles which tuberculous patients had used, those articles should be kept moist, so lessening the chance of dried inoculum being suspended in the air and inhaled.

Dr. Gregory Kayne said there still remained important gaps in the knowledge of the causes and the prognosis of the disease. The two means of prevention were avoidance of contact with tuberculous subjects, and raising the resistance of the individual to enable him to deal with such infection as he might acquire. Antituberculosis measures were not so vigorously adopted in respect of children under 5 years old as in older children. When meningitis developed it was as a complication of the recently acquired disease. He considered the prevention of infection under three headings: (1) adequate treatment of the tuberculous person in the household, (2) hygienic measures adopted in the home, (3) removal of the child from its home. The absence of expectoration was not necessarily an indication that the patient was non-contagious. The value of collapse therapy, especially in bilateral cases, could not be over-assessed. Section 62 of the Public Health Act should be used, he thought, for securing segregation of patients. The increasing of the specific resistance by B C G vaccination he regarded as important; he had seen its results in several European centres. Particularly he would like to see a more energetic study carried out on the handling of home contacts.

IMMUNISATION

Dr. Reginald Lightwood spoke of the special danger of miliary dissemination of tubercle in the infant a few weeks only after its original acquisition. So long as there was no sure way of preventing tubercle in the very young, the separation of the infant from its mother must be considered. The Grancher system was carried out to some extent by the London County Council, and also at Hastings. The great obstacle to the Grancher separation system was the natural objection of the mother to parting with her child at this age; it was also costly. Responsible opinion now seemed for the most part agreed that B C G, properly prepared and properly administered, was harmless, and gave partial immunity when given by the mouth; the date of appearance of the immunity and its duration were still uncertain. Wallgren, administering B C G intradermally in Gothenberg, had apparently achieved such a degree of resistance that among 230 vaccinated infants who had returned to their homes, no deaths from tuberculosis had occurred. The infant mortality-rate from tuberculosis had fallen strikingly in Gothenberg since the intradermal method had been adopted. The special points about Wallgren's work were: (1) no infant was selected for immunisation until it was reasonably certain that it had not yet become infected; (2) no infant was deemed to have been effectively immunised until a positive tuberculin test resulted from B C G vaccination; (3) each case was followed up and, at intervals, subjected to clinical and radiological examination. Parenteral vaccination appeared to confer a more complete immunity than did oral methods.

Dr. Robert Carswell said that the usual division of tuberculosis into tuberculous infection, latent tuberculosis, and tuberculous disease was apt to throw too much into the background the common histological basis. It was now recognised that the Koch preparations T R and B E were agents of undoubted immunising value, which sufficed to eliminate slight or incipient tubercle. How far these would contribute to the eradication or control of the more advanced disease only careful clinical and experimental work could show.

Dr. Leonard Findlay emphasised the seriousness of pulmonary tuberculosis in infancy and young childhood. In 1929 the mortality from the disease in children in the first two years of life was only one-fifth of that in 1911, whereas for persons between 25 and 45 years the diminution had been no more than 50 per cent. In the year 1800 Blackmore found, in a large number of autopsies on children, only three cases of healing tubercle, and not one actual healed case. He did not know whether this great liability to the disease in the very young meant that infants were more susceptible to it, or whether it was due to the more intimate contact of the infant with its tuberculous parents and relatives. It was of supreme importance to take all possible measures to prevent infants from becoming infected. Great authorities had proved that immunity could be harmlessly conferred; the time for discussion had gone, and action on a large scale should be taken.

METHODS OF SPREAD

Sir Leonard Rogers said that during his 20 years as pathologist in the largest hospital in India his attention was drawn to the serious contribution which was made by tuberculosis to the total death-rate. In 5000 post-mortem examinations, tuberculosis caused more deaths than did any tropical disease. Fully 17 per cent. of the deaths were recognisably due to tuberculosis. The peculiar method of living of the Hindoo and his habits usually resulted in each tuberculous subject infecting a number of his relatives before he himself succumbed.

Dr. Veitch Clarke regretted that more stress had not been laid on the need of coördinating the results obtained from the measures available for combating the spread of tuberculosis. He did not think the importance of disinfection could be counted in regard to this disease; any l authority which dissociated itself from disinfectant measures was, he considered, neglecting its duty, especially as so many tuberculous subjects were in the poorest stratum of society. The advocacy of the Grancher system did not take sufficient note of the social and domestic side of life. The diminution in the tuberculosis figures in this country was largely due to general measures such as improved housing and diet rather than to specific measures.

Dr. R. C. Jewesbury said that the practical issue was what one ought to do when a mother, who was perhaps tuberculous, brought her infant to the clinic for advice. To separate mother and child was in most cases practically impossible. Artificial immunisation by vaccination, practised in several countries, had been practically ignored in this. Surely the B C G system of inoculation could be given a trial and the results observed. If the child could be protected from the disease at its most vulnerable age, he might be enabled to carry on to an age when he could tide over a more or less benign attack.

Dr. E. Stalkind spoke of the importance of the social and hygienic factors and of early diagnosing in pulmonary tuberculosis.

MEDICO-LEGAL SOCIETY

At a meeting of this society held on Thursday, April 25th, Judge Erengay presided. Dr. Emanuel Miller read a paper on

The Aberrations of Adolescence

Not till the beginning of the nineteenth century, he said, was there any public conscience aroused with regard to the need for the special treatment of juvenile delinquency. The Children's Act of 1908, with the establishment of children's courts, was the essential landmark in the legal history of the subject. Realisation of the special needs of the child arose from the work of Rousseau and the philanthropic movements of the early nineteenth century, and the advances in medicine and psychology in the second half of that century. Dr. Miller's thesis was that the ignorance of disorders of conduct which had no direct legal bearing had contributed to the distorted picture of adolescent crime, wrong diagnosis, and inadequate methods of treatment. To all intents and purpose, in law, offences and charges were dealt with in the same way, whether they were committed by adults or young persons. Their main concern that evening, however, was with the wide group of disorders of adolescence; the nature of such disorders in so far as they were peculiar to a particular period of human development; the extent to which the diagnosis of physiological, psychological, and sociological causes could help medico-legal experts to interpret the law as it stands; and, lastly, the ways in which they could help to reorientate legal opinion towards a more scientific and more humane attitude to human conduct.

The problem of "growing up" was a difficult one. It entailed for its understanding a realisation that in the same way as the first five years of life were a recapitulation of the main features of racial history, so adolescence was a period of recapitulation of many of the emotional problems of the first five years. Adolescence was a period of the temporary breakdown of integration. Four processes were involved in "growing up" from infancy to maturity. First, there was the power of *inhibition*—that is, the capacity to endure an increasing amount of pain born of frustration of instincts, i.e., the power to subordinate the non-integrated impulse life to the demands of reality which were imposed upon the child by adult standards and social usages. Secondly, there was the process of *translation of ego-centricity* in the child, particularly in matters of love, to ego-centrifugal activities which characterised normal human maturity. Thirdly, there was the *sacrifice of dependency* for self-sufficiency. Fourthly, there was the *acquirement of sexual maturity.*

The coming to maturity of the instincts, particularly of the sex instinct, meant the independence of the human organism as a battling, constructive, sexual, and social creature. At puberty there was a certain discordance or lack of coördination in the growth of the various parts of the body, so that unexpected stresses and strains were placed upon certain tissues, particularly because of the sudden call of the sexual glands and the bony and muscular structures. The greatest discordance occurred as between various mental functions—instinctual, emotional, and intellectual. Instinctual functions made demands which could not be met adequately by the moral forces already established with some degree of strength in earlier years. Adolescence presented therefore a picture of instinctual, moral, and intellectual incoördination as well as of concomitant physical disorders. Autoerotism, sadistic, and masochistic manifestations occurred along with moral compulsions; idealism and family devotion with rebelliousness and revolt against authority; and sexual reserve and asceticism alongside delinquencies which were sometimes but feeble disguises of sexual frustrations. Some suicides were explicable only on understanding these mental mechanisms. Examples could be quoted of masochistic exercises ending in death, yet called suicide. Dementia præcox, not as a clinical entity but as a profound regressive phenomenon, was of first importance to the study of adolescence, and manic depression, though rarer, was also an indication of the severity of the moral conflicts of adolescence. Vagrancy, compulsive delinquency, and social stupidity were made clearer in the light of psychopathological concepts which the law could not afford to ignore. The occurrence of precocious adolescence and delayed adolescence showed how difficult it was for the law to deal adequately with young offenders only up to 17 in the children's court. Sentences should be therapeutic and not framed solely according to a legal rule. Justices should know more of the curative aspects of penology; law students should have a working knowledge of psychopathology; and probation officers should have facilities for studying a wider field of disorders than those adolescents who reached the courts. Observation centres were much needed.

Discussion

Dr. Letitia Fairfield said it was necessary to keep the age of the children's courts to 17, as it was undesirable to try young children with the developed young criminals of both sexes. Psychological treatment was only possible with full coöperation of the offender.

Dr. H. R. Oswald said that as many offenders were mentally defective, sterilisation should be seriously considered, or alternately such offenders should be treated like lepers.

Dr. A. Baldie said that the subject of juvenile delinquency went far beyond the confines of mental defect. Many adolescent disorders were the product of vigorous personalities who needed guidance and not segregation.

REVIEWS AND NOTICES OF BOOKS

The Cyclopedia of Medicine

By Various Contributors. Editor-in-Chief: GEORGE MORRIS PIERSOL, B.S., M.D.; Assistant Editor: EDWARD L. BORTZ, A.B., M.D. Philadelphia: F. A. Davis Company. 1934. Twelve volumes, about 1050 pages per volume. $120.

THIS comprehensive work of reference has now been completed by the publication of Vols. X., XI., and XII., and a separate index of over 400 pages. It deals with medicine and surgery and all the specialties, being written by a very large number of experts, mostly from the United States and Canada, but some from Europe and South America. The matter is arranged alphabetically, and is treated both from the practical and academic points of view. The work is ambitiously designed to meet not only the needs of the general practitioner but those of the specialist and the laboratory worker also. The editor sees the gulf between these groups as steadily narrowing with the advance of scientific medicine; it might be argued with equal force that their scope is being differentiated by the growing complexity which this advance brings in its train. Throughout the work the aim is to approach medical problems as far as possible from the bases of pathological physiology, physical chemistry, and biophysics. Some disturbances of function are considered separately—e.g., asphyxia and dyspnœa, and the production of œdema. References to the literature, sometimes very extensive, are given at the end of most of the contributions and abstracts of recent papers are often quoted in the articles. In Vol. X. are included the subjects of pregnancy, psychology, and radiology, the last occupying 400 well-illustrated pages. Vol. XI. contains among other important articles a well-written account of stomach disorders, and Vol. XII. is notable for an authoritative presentation of the subject of thrombo-angiitis obliterans, and a description of pulmonary tuberculosis from all aspects (except that tuberculous empyema does not appear to be adequately considered), including a lucid account of the X ray diagnosis. The good impression made by the earlier parts of the work is maintained.

It is inevitable when experts combine to write on a single or related subjects that some overlapping and some variations on the same theme are to be found, but on the whole readers will not find this a disadvantage in a work which is comprehensive and authoritative. It is proposed in the future to issue supplements to cover all important developments, and it will be interesting to see what changes are selected as worthy of record.

The Rheumatic Diseases

Practitioners' Series. By G. D. KERSLEY, M.D. Cantab., M.R.C.P. Lond., Assistant Physician at Royal United Hospital, Bath. London: William Heinemann (Medical Books) Ltd. 1934. Pp. 88. 6*s*.

THIS little book sets out in a concise straightforward fashion much useful information about the rheumatic diseases. It deals with facts and not with theories and should prove valuable to students and practitioners, although consultants will find interesting information in the chapter on physiotherapy. The opening chapters give an excellent summary of our scanty knowledge of the ætiology of the rheumatic state in children and young adults. Then follows a chapter on rheumatoid arthritis, with a particularly helpful paragraph on treatment. The chapter on fibrositis is one of the best in the book and should be of help to the practitioner in his dealings with this extremely common, painful, and disabling group of conditions. There follow sections on osteo-arthritis, climacteric arthritis, spondylitis, and gout, with an excellent chapter on physiotherapy; a short account is given of the individual British spas. It must be admitted that at most medical schools the attention paid to this important group of diseases is still inadequate to the needs of those who are entering general practice, and the student would be wise to use this short text-book to supplement his teaching.

---

1. Ophthalmology in General Practice

By O. GAYER MORGAN. London: John Bale, Sons and Danielsson Ltd. 1935. Pp. 58. 2*s*. 6*d*.

2. Aids to Ophthalmology

Eighth edition. By N. BISHOP HARMAN, M.B. Cantab., F.R.C.S., Consulting Ophthalmic Surgeon, West London Hospital; late Ophthalmologist L.C.C. Education Department. London: Baillière, Tindall, and Cox. 1935. Pp. 242. 3*s*. 6*d*.

1. Mr. Gayer Morgan's useful, well-written, and compact little book deals with conditions frequently recurring in private practice and those less common ones in which early and accurate diagnosis is of vital importance to the eye—the ophthalmic emergencies. Of these emergencies the most important are acute glaucoma and penetrating wounds of the eye, and accordingly the methods of using the focusing lens, the loupe, and the binocular magnifier are carefully described, as well as the conditions which familiarity with these simple aids will enable the general practitioner to diagnose and to treat. For these purposes ophthalmoscopic diagnosis is not required; but modern electric ophthalmoscopes are so easy to use that every practitioner ought to be able to diagnose ordinary fundus appearances and to distinguish the normal from the abnormal. Some of the conditions which he should be able easily to recognise with the help of this book are choked disc, optic atrophy, the conditions of the retinal vessels due to arteriosclerosis when well marked, and detachment of the retina. It is, of course, essential that the practitioner should be able to recognise the first signs of ophthalmia neonatorum and apply the correct treatment. The importance of the early diagnosis of squint in young children is not so generally appreciated. Mr. Morgan's little book should serve as a standby to many who have had no time to include a serviceable knowledge of the eye in their pre- or post-graduate studies.

2. Mr. Harman has succeeded in bringing his little text-book abreast of the times while keeping it so small and cheap as to suit every pocket and purse. Comparing it with earlier editions, we notice that the chapter on eye signs in body diseases gives the student a glimpse into the wider implications of the subject, and one on the incidence and causes of blindness introduces a subject of growing importance. A new chapter on standards of vision for the Services will be found useful for reference. Mr. Harman calls attention to the hæmatologic diagnosis of sympathetic ophthalmia in cases which show an excess of large mononuclear cells, and to the treatment of such patients with salvarsan. The newer operations for detached retina are recorded, and the uses of

slit-lamp are indicated, the author's own hand model being figured. In the chapter on operations Mr. Harman's subconjunctival reefing operation for squint is fully described. The bulk of the book remains as it was, every page containing matter which the student requires to know and nothing superfluous being set down. The number of new illustrations in this edition is 38. It also includes an excellent first guide to the practice of refraction with useful practical hints on the prescribing of glasses. The only slips we have noticed are the attribution of obstruction of the central artery of the retina to embolism alone, and the repetition on p. 183 of a sentence from a previous chapter.

L'année thérapeutique, 1934

By A. Ravina. Paris: Masson et Cie. 1935 Pp. 191. Fr.18.

Dr. Ravina continues to write these attractively produced little volumes. Like last year's annual, this one contains about 80 short accounts of new methods of treatment, based on papers published during the year, mostly in France, but sometimes elsewhere. The accounts are essentially abstracts of the papers, full enough to enable the reader to judge, approximately at least, the evidence on which advocacy of the various procedures is based. The subjects are diverse, ranging from evipan anæsthesia and the use of large doses of iron in hypochromic anæmia, to the treatment of the Vaquez-Osler disease with raw onions, and the plugging of bleeding tooth-sockets with the pectoral muscle of freshly killed pigeons. Only occasionally does Dr. Ravina permit himself a brief, and usually cautious, word of comment, and there is nothing to imply recommendation of the treatments he has chosen for description. He merely answers the question "What is new in the way of treatment?" and leaves his reader to judge what is worth while.

Quarterly Journal of Medicine

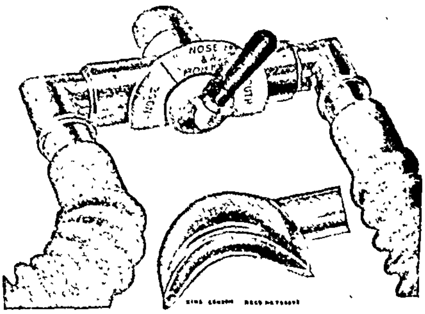
The current issue (April, 1935) contains several papers of unusual interest. E. A. Cockayne, David Krestin, and Arnold Sorsby report fully the history of two families exhibiting the Laurence-Moon-Biedl syndrome; the text is illustrated by fundus drawings and there is an extensive bibliography given.—Hugh Ramage and J. H. Sheldon give the results of their research into hæmochromatosis. They have examined the organs and tissues post mortem of five cases of this disease in order to discover the distribution and quantities of the deposits of iron and sulphur in excess over the normal. Their figures for the sulphur content differ considerably from those of Loeper, Ravier, and Lesure. They further estimated the copper and calcium content by means of the spectroscope.—G. C. Linder has investigated the influence of infection on the action of parathyroid hormone in man; the method was to estimate the serum calcium and its response to Parathormone injections in cases of typhoid and pulmonary tuberculosis. From the results no general rule could be formulated.—Crighton Bramwell has analysed by means of graphic records the sounds and murmurs of auricular systole. He is able to demonstrate that the initial vibrations of the first heart sound are produced by the auricle and not by the ventricle, and that the auricular sound is not entirely due to a muscle tone but in part at least to vibrations set up by the blood ejected by the auricle. He has also studied gallop rhythm, reviewing the clinical findings and after-histories in a consecutive series of 62 cases in which the sign was present. He puts forward a hypothesis regarding the mechanism of production of this rhythm.—R. S. Aitken and C. Wilson have attempted to demonstrate a pressor substance in the blood in malignant hypertension, similar to the one described by Bohn. They were unable, however, to confirm Bohn's claim.—S. Levy Simpson contributes a paper on secondary pellagra in which he establishes a relationship between pellagra and adrenal hypofunction and describes the mechanism by which the condition is produced.—R. S. Handley and A. M. Nussbrecher give details of a family in which the classical symptoms of hæmophilia appear in women and review the literature of hereditary bleeding in women.

NEW INVENTIONS

APPARATUS FOR GAS ANÆSTHESIA

When gas is administered for dental operations time is lost while the face-piece used for induction is being removed and a nasal tube adjusted. Our object has been to avoid this delay.

The apparatus, which can be adapted to any satisfactory gas machine, consists of two delivery tubes emerging from a head with a three-way valve. This makes it possible to deliver the anæsthetic gases to the mouth only, to the mouth and nose simultaneously, or to the nose only. The mouth delivery tube ends in a metal inhaler of special design which allows easy access to the nostrils when it is in place. The nose delivery tube ends in an attachment to accommodate either a standard nasal inhaler or a nasopharyngeal tube. Anæsthesia is induced by administering the gases through the mouth with the valve turned to "mouth only." A mouth-prop is inserted, the patient is asked to breathe easily through the mouth, and any nasal breathing is checked by gently compressing the nostrils. After induction anæsthesia can be maintained while the pharyngeal catheter is passed through the nostril or nostrils and secured in place. The gases are then passed through nose and mouth simultaneously for a moment while anæsthesia is steadied. The valve is turned to "nose only," the mouth inhaler is dropped, and the mouth is packed with gauze in preparation for the operation.



The advantages claimed are: (1) the nasopharyngeal tube can be passed without undue haste; (2) resort to ether, or ethyl chloride, is unnecessary; (3) simpler nasal tubes, such as Boyle's tubular nose-piece (two curved metal tubes for insertion into the nostrils), can be used; (4) the mouth inhaler materially assists in obtaining induction if the ordinary type of nasal inhaler is used; and (5) the wide-bore supply tube to the mouth inhaler allows of rapid induction without the feeling of suffocation or discomfort associated with small-bore tubing.

The apparatus has been made by Messrs. Charles King Ltd., Devonshire-street, London.

H. Parry Price, M.R.C.S. Eng.,
Reading. G. H. Ellingham, L.D.S. Birm.

THE LANCET

LONDON: SATURDAY, MAY 4, 1935

The peace which has prevailed in our constitutional affairs during the rule of His Majesty George V. has been unbroken, and his claim on the affections of his subjects, always amply proven, receives next week a full demonstration. While other principalities and powers have gone down, to disappear or rise again in altered shapes, the King governs a united Empire and every national activity must have benefited, and must be benefiting, from the justice and stability of his reign. When the calling of medicine is in question such a period as 25 years presents a problem in retrospection. The period is a considerable one, long enough to leave deep imprints upon the path of progress, but not long enough to make any surmise certain as to what details of the progress will be found later of permanent value. It so happens that the span of professional life of both the physician and the surgeon to His Majesty's Household coincides broadly with that of his reign. The retrospects which follow from their pens supply unanswerable reasons for a belief that our medicine will maintain, and enhance in virtue, what of fundamental good lies in the efforts of the past 25 years, while subjecting all developments in our science to a scrutiny which until recent years has been undreamt of. Dr. Ryle, physician to Guy's Hospital, and Mr. Walton, surgeon to the London Hospital, from different angles, testify to a spirit of scientific union in the ranks of medicine which must promote the consolidation of all that we would have kept, while forming the firm foundation for the rise of greater things in the future. The fusion of ideals and of interests among those in charge of the health of the country has become a very real thing, and the creation of that fusion is the conspicuous characteristic of medicine during the past 25 years. The profession of medicine, when joining all ranks and classes in loyal congratulation to King George and Queen Mary upon the jubilee of their reign, can point with honourable satisfaction to real advances made under their administration, and to a vast vista of promise.

MEDICINE 1910—1935

By John A. Ryle, M.D., F.R.C.P.

PHYSICIAN TO HIS MAJESTY'S HOUSEHOLD

I

To have lived the more active part of one's life within the first 25 years of the present Georgian era, observing and sharing, in however humble a degree, its manifold changes and reactions, confers on review a deep sense of privilege. For medicine it has been an eventful era. The medical sciences, in concert with other sciences, have registered a proud succession of discoveries, while medical practice has been both enriched and embarrassed by the rapidity of progress and accumulations of new method.

Beside me as I write I have the 1910 edition of "Osler's Medicine" and a modern text-book. The first remains a classic and a rich mine of clinical information, but, lacking wide tracts and chapters embodied in the second, which relate especially to developments in the diagnostic fields of radiology and biochemistry, it has become inadequate. In 1910 I was a clinical clerk in the wards in which I now teach. The reports which we handed to our teachers then were rarely weighted with the sheaves of documents from chemist, bacteriologist, hæmatologist, radiologist, and clinical specialist which my own clerks now assemble. I am grateful to have lived and to have been taught in that easier period by men trained in the tradition of the physician-pathologists for which my school is famous, and I still believe, as they and Osler believed, that the bedside, the out-patient department, the dead-house, and the practice which comes later must continue to provide the chief foundations of our medical art. The problems of man in disease will always require for their solution processes additional to strict scientific assessment. I commiserate the present generation of students on the score of the size and complexity of their curriculum and the difficulties which they must experience in combining and applying their departmental knowledge. I envy them, on the other hand, for their superior endowments in chemical understanding and for the inspirations of the times in which they live. Between them they have already witnessed the introduction of insulin and liver therapy; the much more effective handling of the secondary anæmias; the more certain and earlier recognition and control of many disease-processes with the aid of blood chemistry; the more intelligent applications of psychology, supplanting the electricity, bromide, and valerian of an earlier day; and many advances due to better medico-chirurgical coöperation.

It would also, I believe, be fair to say that the relationships between teacher and student have become more free and friendly. Instruction is less didactic and authoritative and open discussion is more commonly encouraged. Rapid increments of knowledge, for all the help which they have given, have however made new difficulties by increasing the number of possibilities and inquiries to be reviewed in the problematic case. Certainty and completeness in diagnosis appear less easy of attainment than they did when precise checks and controls were lacking. On the whole there is more humility both among teachers and students. In therapeutics conflicting views, especially where there are medical and surgical alternatives, complicate judgment, while the multiplicity of theories and remedies which infiltrate the mind by way of individual teaching, the journals, and the advertisements of the proprietary chemists are a constant embarrassment.

The growing habit of intensive specialisation has been good for the special subjects and has brought benefits to countless patients, but for the time being its influence upon medical thought and practice as a whole and upon undergraduate teaching has not been altogether good. Inevitably it has encouraged men to ignore that close interdependence of part and whole and environment to which the biologists and the philosophers have become increasingly attentive in recent times.

II

It is impossible to estimate our indebtedness where diagnosis is concerned to modern radiology, endoscopic methods, and biochemistry, or to the many therapeutic improvements in the fields of special surgery, pharmacology, and dietetics which the past quarter of a century has brought. We are, however, an impatient profession and liable to queer crazes and misapplications of our science. I do not wish to overstress the abuses which have followed new knowledge and technical advantage, but be it remembered that within the era under review, and especially its post-war phase, we have witnessed the misapplication of bacteriology in a riot of ill-considered vaccine therapy; the arrival and, let us hope, the departure of unhealthy experiments in amateur psychiatry and analysis; and the rise and fall of a crude mechanistic surgical epoch leading to excessive operating especially in the abdominal field. It is, however, remarkable and gratifying that within this same brief era we are already observing the return to sanity and balance. We are testing our new tools and using them to fuller and fuller advantage. We are more frequently allowing science to correct our art, and more rarely permitting our art to bring discredit on our science.

It becomes daily more apparent, however, that something more than a revised curriculum will shortly be needed to set our professional house in order. The standards of general medicine must be improved even if it requires such educational changes as the postponement of the more specialised studies until after qualification, or the addition of a few months spent in apprenticeship to experienced general practitioners before qualification. Better facilities are needed for obtaining qualified hospital appointments both before and in conjunction with practice. To balance the inevitable and necessary multiplication of specialists we require, as a leaven, a larger proportion of well-trained general physicians and a higher average of culture and attainment in the coming generations of students destined for general practice. The public has been partly to blame for present dissatisfactions by reason of its own over-insistence on specialist advice; credulous ever and avid of the newer mode it is not aware that the maladies and problems of our forbears were commonly far better handled by general practitioners of the old humane, if less scientific, school than they are to-day by multiple tests and X rayings and visits to a succession of consultants. Important innovations in municipal and State medicine have added to the difficulties of practice by a gradual withdrawal of much work, with its attendant experience, which formerly belonged to the family doctor.

III

The last 25 years of medicine may conveniently be divided into three periods, 1910–1914, 1914–1918, and 1918–1935. In the first period teaching was predominantly broad and clinical, soundly backed by morbid anatomy and histology and the valuable additions to diagnosis which bacteriology had supplied. The Wassermann reaction had recently arrived and the arsenical treatment of syphilis had been discovered. Laboratory medicine and diagnostic radiology, as we now employ them, were in their infancy. There had been no big changes in the medical systems of the country apart from those due to the Insurance Act, which brought both advantages and disadvantages in its train.

In the second period those who were so situated as to gain their war experience in hospitals and clearing-stations received what was in fact a new medical education. The treatment of wounds and fractures, intensively studied on a vast scale, was improved beyond belief. The pathology of wound infection and the treatment of chest and head wounds received combined study at the hands of surgeons, physicians, radiologists, and pathologists with the happiest results. The protective uses of typhoid inoculation and of the early administration of tetanus antitoxin were proved and justified to the hilt. Blood-grouping and transfusion came into their own. Tropical diseases, the effects of gassing, and "new" diseases such as trench fever, trench nephritis, and spirochætal jaundice were subjected to intimate investigation by team-work of a highly productive kind. At home the study of the "soldier's heart" gave a new impetus to cardiology, and the study of the war neuroses laid the foundations of much that is good in medical psychology in this country to-day.

Where all else was destructive it is something to remember and be proud of that the medical services did not fail in any part of the reparative work allotted them and that, simultaneously with the performance of arduous humane and military duties, they advanced knowledge by patient observation and research and added important chapters to British medicine.

One of the most effective developments of war-time medicine was what came to be known as team-work. Unhampered by any considerations of career or livelihood, and stirred alike by the spirit of the times and enthusiasm for their patients and their subject, the members of medical, surgical, and mixed teams at work on the various fronts applied themselves unanimously to their tasks in a manner which seldom seems possible in civilian medicine to-day. An historic example of the benefits of applied "team-work" was provided by the King's illness, in all the details of the investigation and conduct of which reminders were forthcoming of the combined medical and surgical treatment of chest wounds with pathological controls which took place in the clearing-stations and base hospitals in France.

In the medical schools and special hospitals it is difficult, where it might seem easiest, to secure this intimate and happy coöperation. The claims of teaching and practice and other routine and problems of administration all militate against full success. The Medical Units, which have brought new motives into teaching and have given facilities for full-time workers, have other concerns and are not, as units, sufficiently representative or full time. An approach to the system has been attempted in certain private clinics whence valuable publications are occasionally forthcoming, but still the spirit and achievements are not comparable and the field of opportunity is too confined. If ever there were an opportunity to recapture the team-work spirit under suitable conditions this should, to my thinking, be found in the newly organised hospitals of the London County Council and the larger municipalities. Whole-time workers, relief from the necessity of practice and teaching, and unlimited material, with facilities for segregation of groups of cases, are the main essentials. In closely collaborative team-work is to be found the best answer to the artificial separations of medicine, surgery, and the ancillary sciences.

Of the post-war period I have already written partly in praise, partly in criticism. Medical philosophy has not prospered commensurately with medical science and technique. During the awkward years of reconstruction between 1918 and 1935 misdirections of thought and energy inevitably occurred, but they are already being remedied, and British medicine, as compared with the medicine of other countries, has maintained its general high level and has recorded significant gains. The yearly reports of the Medical Research Council make important reading. Neurology, psychiatry, cardiology, and pædiatrics have registered steady progress. "Clinical science" has been launched. There is scarcely a branch in which advances have not been made. Even in the difficult cancer problem new ground has been consolidated. The incidence of preventable diseases continues to fall. The toll of human life and suffering in acute and chronic diseases formerly beyond efficient aid has steadily diminished.

The year of the King's Jubilee, which has provided a fitting occasion for review, may well mark the initiation of a further phase of eager effort and fruition, affecting alike the science, the art, and the teaching of medicine throughout these islands and the dominions over seas.

SURGERY 1910—1935

By A. James Walton, M.S., F.R.C.S.

SURGEON TO HIS MAJESTY'S HOUSEHOLD

I

When a man's opinions become fixed his progressive work is finished. Vanity, which increases with age, shows a constant desire to prove that views expressed long ago are still correct. Only as long as a man is prepared to admit that his previous conclusions have been shown by the light of more recent knowledge to be incorrect is his mind young, active, and receptive. No surgeon therefore can ever feel that his knowledge is complete, for ever he must keep abreast of new knowledge and must be analysing his own results and comparing them with those of others. He must be altering his views and his treatment in accordance with these observations. It is often stated that surgery has now reached its limits and affords but little chance for progress, that treatment and investigation have become standardised and almost beyond discussion. If those who are depressed by such views would realise that even to-day there is hardly a single statement in surgery which can be made without fear of contradiction they would again take heart and feel that they also have a good opportunity of adding to the common stock of surgical knowledge. Perhaps nothing offers greater encouragement than to look back over a period of years and to observe the changes that have occurred during that time. Some of them may not be regarded by all as moves in the right direction and many of the older methods that have gone may be regretted, but there can be no doubt that more has been gained than lost for the common good.

The present time of His Majesty's Jubilee is a fitting one to look back and observe what progress if any has taken place during His Majesty's reign. Such a review reveals the fact that the changes have been very extensive, as they have been in every branch of civilisation. The whole period has been one of flux. As H. G. Wells makes one of his characters say, "This here progress, it keeps on. You'd hardly think it could keep on." It is so interesting a period in the history of the human race that even the most weary and jaded of us could almost hope for great prolongation of life to see in what direction we are moving. Much of the present may be depressing and unpleasant but there is also much to make us believe that we are not rushing to destruction and dissolution but are ultimately reaching to a higher and brighter life. In surgery this certainly seems to be the case and many lives that were doomed to a rapid termination or to years of misery are now saved, and their owners have been given years of comfort and happiness.

II

It is in the atmosphere and life of a large hospital that the changes are most in evidence, and that which would, perhaps, be most noticeable to one who has not visited his hospital for 25 years is the status and attitude of the surgeon not only to his patients but to his colleagues, medical officers, and students. In the first years of this century surgeons were regarded with awe and almost with reverence. They were individualists, ruling their own departments with an almost regal authority. Their knowledge was omniscient and their views infallible. On their arrival they were met in state, and in state they progressed round the wards. Their teaching was a combination of dogma and sarcasm concerning the views of others. They laid down the law with great authority but produced little proof of their statements. Their opinions were never questioned and to admit an error was considered as evidence of lack of knowledge. As a result they often came to believe in their own infallibility. They rarely met their colleagues, of whom they were often bitterly jealous, and although treating them with formal courtesy in their company were only too willing to belittle their work in the presence of students. They regarded all workers in the few laboratories that then existed as their servants. Theirs were the patients and all who worked among the patients were under the surgeon and his was the credit of their work. With such an attitude there was a grave risk that all work by others should be neglected and that when the surgeon retired his knowledge of surgery might be but little altered from that which he held on the day of his appointment.

III

Gradually and almost imperceptibly this has all changed. The individual surgeon is treated with much less awe and his work is subject to the keenest criticism, both during his clinical teaching and in the medical press. He is expected to produce proof of all statements in his writings and he must be prepared to be questioned on his remarks by any audience. His operating theatres are open to medical men from all parts of the world and while operating he must be ready to answer all questions on his technique and to state why he adopts one form of operation in preference to others. It is the presence of this critical environment which perhaps above all else compels a surgeon to keep up to date and to study his own results in comparison with those of other surgeons. On the other hand, his colleagues on the clinical staff, in the laboratories, and in the special departments, and his assistants in the wards are all his personal friends. He treats his colleagues with very little formal courtesy, but he knows that he can rely on their help even in the slightest difficulty. The cases are not jealously guarded as the personal property of the individual surgeon, but opinions are freely invited and patients are often transferred to the surgeon who has the widest experience and the greatest interest in that disease. And he no longer feels that it is derogatory to admit that others know more on one subject than himself; the advice of the most junior colleague is as eagerly sought as that of the senior. It is still to-day the greatest compliment to be asked advice by one's colleagues, but it is also the greatest satisfaction to seek it from others. Not only are the laboratories freely at the disposal of any surgeon wishing to work in them, but the greatest help and advice is willingly given by the heads of these departments. Young men working under a surgeon have every opportunity of making use of his clinical material and are encouraged in every way to carry out research work and to publish it under their own names. The surgeon realises that he can learn more and obtain more encouragement from the keenness and enthusiasm of younger men than from any other source. The present-day surgeon may have lost much of the old formality, but what he has lost in formality he has gained in friendship. He is no longer an individual worker for his own advancement, but a member of a large team working for the common good. This growth of team-work is becoming more and more necessary in private as well as in hospital work, and surgeons are finding it essential, especially in the larger operations, not only to operate in the same theatre but to employ the same anæsthetist, assistant, and theatre sister. The greatest admiration must be expressed for the older surgeons who worked with no skilled aid and with no conveniences, but the best results can only be obtained in the modern extensive operations with the help of a skilled and highly trained team.

IV

In the ordinary practice of surgery much advance has been made. Certain diseases which had a more or less hopeless outlook are now successfully treated and the patients' lives are saved. Tumours of the pituitary gland were rarely operated upon. Nothing was known of the surgical cure of hyperparathyroidism. Hyperthyroidism was only rarely treated by operation, and not only was the mortality very high but the value of operation was disputed by many. I once heard a famous physician state that it was as sensible to operate upon a thyroid for Graves's disease as to remove a kidney for diabetes. Splenectomy was rarely performed, and gastrectomy and colectomy for carcinoma were in their infancy. Perhaps however the greatest changes are those seen in the nature of the hospital population. Before 1905 the wards were filled with patients suffering from large ulcers of the neck due to tuberculous glands which had been opened and scraped. Excisions and amputations for tuberculous joints and bones were to be found on the operating list nearly every day. To-day such cases have almost disappeared and the majority of students pass through their whole career without seeing a case of operation for tuberculous glands or joints. Acute appendicitis was with us then as it is now, but the mortality with acute cases was nearly 80 per cent. The use of surgical gloves had only just been introduced and suppuration or even fatal sepsis was not uncommon after clean operations. But although we hear so much to-day of the marvels of modern surgery, there can be no doubt that the greatest progress has been made in what is the real aim of medicine, namely, preventive medicine. Not only has surgical tuberculosis greatly diminished, but typhoid fever which was so common before 1910 is now rarely seen in hospital. In the summer months of that period 40–50 children a day were sent away from a hospital to die, being already moribund with epidemic diarrhœa and vomiting. To-day these cases are rarities. Such great advances have been made owing to control of food, water, and sanitation that one can be certain that the disappearance of other diseases will follow in their wake. In days to come surgeons will look back with astonishment at the modern operations for appendicitis, for gastric and duodenal ulcers, and for carcinoma, and when the cause of the hyperactivity is known and prevented it will seem inconceivable that the enlarged thyroid of Graves's disease was ever removed by surgery. Medicine will ultimately progress so that surgery reaches its true aim, that of its own abolition. Already surgeons have ceased to be mere technicians and are physicians in their own specialty, and it would seem that one day the cleavage between medicine and surgery will cease and men will become specialists covering every branch in their own subject.

V

The progress of medical education is as great but is less well-defined and probably in a few years will undergo considerable further change. On all sides this subject is bristling with difficulties and is exercising the minds of teachers. Unfortunately in many respects the most satisfactory treatment of the patient is conflicts with the best teaching of the undergraduate student. Throughout medicine and surgery the introduction of more detailed methods of investigation and the increase of technical skill in treatment have led to the wide growth in specialism, so that more and more departments are established which the already overworked student has to attend. An undergraduate working for a pass degree requires to know *when* to operate and not *how* to operate, and yet a great deal of his time has to be taken up attending and assisting at prolonged and complicated operations which he ought never to be called upon to perform in general practice. Probably in a short time this part of his work will be delegated to post-graduates specialising in surgery. The enormous growth in clinical laboratories has led to much more reliable and intensive investigations of a biochemical and pathological nature and to-day has become essential for the investigation of most diseases; but it has removed from the student and the resident medical officer the feeling of responsibility which was so useful in his teaching and in his training of self-reliance. It has also added to his difficulties in that special classes have to be arranged for his training in clinical pathology. With the appointment of officers of higher training as skilled assistants his opportunity of carrying out minor operations has been lessened, so that post-graduate appointments have become increasingly important until they are now essential. It is difficult however to see how this can be avoided. Increased knowledge necessitates increased training.

Although there is therefore still much in surgery that is unstable and is bound to change, the many improvements that have occurred in the last 25 years show great progress. Surgery is international, and team-work has replaced individualism. Every man has increased powers of learning from those in his own country and abroad, powers which have been enormously enhanced by the growth of travelling, surgical clubs, and of medical societies, where all branches meet for free discussion, so that even the humblest worker who has no opportunity for research may throw a side-light on a subject which may lead to most valuable results. Every student who enters surgery to-day may feel that although his income may be less than in the past he will be able to make a living and will have that which will give greater happiness in life than financial profit—interesting and joyful work. And that he has, more than ever before, opportunities of making new discoveries and adding to the general progress of medicine.

ANNOTATIONS

THE PRACTICE OF PSYCHOTHERAPY

A LEADING article in our issue of March 16th, dealing with the difficulties surrounding the practice of psychotherapy, has called forth in our correspondence columns the expression of varied opinions, scarcely any of which seem to have escaped challenge. This state of affairs, at first sight depressingly suggestive of some inherent difficulty in the subject itself, resolves itself, on close examination, into the stimulating discovery that the subject is being approached by different people, not merely from different angles, but from different ends, whilst the absence of controversy about methods of treatment should be noted as marking an important advance. The modern psychiatrist, who by his change of title indicates a wider field of effort than the older alienist, seeks to take into that field the treatment of those disabling mental disorders which do not typically lead to the need for institutional care and are more accessible to psychological treatment than are the major psychoses. Approaching the subject from this end, and familiar with cases where delicate diagnosis may be necessary to avoid attempts at treating unsuitable patients, the psychiatrist regards experience in the major psychoses as an important element in the preparation for psychotherapeutic work. Hence we find one correspondent demanding the diploma in psychological medicine as a minimal requirement for those handling mental patients; and it must be admitted that the diploma, or a doctorate in mental diseases, is the only hall-mark available for the would-be psychotherapist. The requirement is, however, vigorously contested by a correspondent who declares that medical psychology is as fundamental to medicine as is physical examination, and sees no reason why any practitioner who has the time and inclination for the work should not practise psychotherapy. Here we note the approach to the subject at the end remote from psychiatry, and as a practical example of this approach may be cited an article by Dr. James L. Halliday on Psychoneuroses as a Cause of Incapacity among Insured Persons.[1] Dr. Halliday, whilst acknowledging his debt to psychiatric writings, used the methods of ordinary clinical medicine in demonstrating that over 30 per cent. of incapacity in insured persons was caused by psychoneurotic illness, most of it masquerading under other diagnoses. Though he did not touch on actual psychotherapy, he pointed out the need for an "integrator," a rôle to be played by "a general practitioner who will have been trained to recognise the elementary reactions of a person to the difficulties, including the happening of an organic disease, which must be encountered by everyone who passes through the ever-challenging environment of being alive." The context indicates that Dr. Halliday hopes for a reorientation of the medical curriculum which will enable the practitioner to fill this rôle.

These alternative avenues of approach explain the conflict referred to by one writer, rightly or wrongly, as "the silent contempt that now obtains between the institutional and the non-institutional psychiatrist." We must note at this point that the conflict expresses itself, as such conflicts often do, in a matter of nomenclature. The word *psychiatrist* may be, and often is, taken to mean a person engaged in asylum work as his chief interest; some non-institutional psychiatrists would repudiate the title, whilst asylum workers might deny their right to it. The word *psychotherapist* carries with it no claim to special acquaintance with asylum work and the two titles serve to indicate the roads by which their respective bearers have come near enough to be aware of their differences. There are psychotherapists who, beginning with the psychoneurotic as he is found in general practice and obtaining their training as best they can, whether by personal analysis or otherwise, gain—perhaps by their own mistakes—a knowledge of early psychotic cases at a stage before they reach asylums. If they are wise such practitioners will know when to seek the aid of the experienced psychiatrist; nor can it be denied that a short experience of asylum work would be helpful to them. On the other hand, the asylum worker who turns to the treatment of psychoneurotics will have much to learn from his non-institutional colleagues. Coöperation between those who have approached this important subject from different beginnings should be made easier, we hope, by the ventilation of their views in our columns.

ALVEOLAR VENTS IN THE LUNG

ANATOMISTS are still divided over the histology of the terminal portions of the respiratory passages. A. C. Macklin, who formerly upheld the view that the mammalian airways end blindly, has now recanted[2] in favour of those who describe minute pores, stomata, fenestræ, or (as he prefers to term them) vents, connecting adjacent alveolar sacs. Thick sections appear to be necessary for satisfactory histological demonstration of these vents, which vary in number and size in different species of mammals, their width ranging from that of a red blood corpuscle (or even less) to half that of an alveolar wall. He has demonstrated them in the lungs of human beings aged from 29 months to 80 years; apparently, therefore, they are not pathological in origin, although an emphysematous ætiology has been ascribed to them in some quarters, and their formation certainly resembles the changes of emphysema in that they must be formed by breaking-down of septa between adjacent alveolar spaces. Not only has Macklin converted himself to the histological proof of the existence of these vents, but he describes experiments which leave no doubt that there is free peripheral communication between lobules of the lung. Possibly the object of this communication is to equalise alveolar air pressure in adjoining lung territories, and where air-tubes are occluded it may help to prevent lobular atelectasis by allowing air to reach alveoli whose supply is otherwise cut off. It seems likely, too, that the vents act as safety-valves to prevent harmful over-distension of alveoli adjoining a territory threatened with collapse. In such circumstances they would doubtless widen so as to allow freer escape of air into the under-distended region; indeed, Macklin thinks that as a rule the smaller air vents are actually closed and do not open unless the alveolus is over-full. On the debit side is the possibility that they enable infected material (e.g., tuberculous) to spread from lobule to lobule—the process being encouraged by excessive distension of the alveoli and consequent enlargement of the vents spread from alveolus to alveolus through the pores.

SUPPLEMENTS TO THE DIET OF CHILDREN

IN an investigation reported by T. W. Simpson and Eric C. Wood[1] forty-eight children attending welfare centres were successively treated, according to a controlled experimental scheme, with cod-liver oil, halibut-liver oil and milk, and Virol, in doses of equal calorific value. Each child was under observation for twenty-four weeks—six weeks on its ordinary home diet and six weeks on the ordinary diet plus each of the supplements in turn. The growth-rate was measured by weekly weighings. Six weeks may be thought hardly long enough for the determination of the benefits, or lack of benefits, derived from the supplements, but Simpson and Wood state that preliminary experiments showed that four weeks' treatment was sufficient to produce an appreciable variation in weight, and in the main experiment distinct differences appear. The mean increase in weight per child for the six weeks' treatment was 1·84 oz. on the unsupplemented diet, 5·98 oz. with the addition of cod-liver oil (two teaspoonfuls daily), 6·94 oz. with the addition of halibut-liver oil (six drops daily) plus half an ounce of dried milk, and 15·88 oz. with the addition of virol (three teaspoonfuls daily). Taken as a whole, the results clearly suggest that benefit was derived from the supplements, but inspection of the figures subdivided by sex and period of treatment shows that the differences in results with the different diets are far from uniform; possibly, however, this is due to the small number of children involved. With the diet containing halibut-liver oil the investigators found significantly greater individual variations in growth than with that containing cod-liver oil, and they conclude that the accepted dose of halibut-liver oil contained too much vitamin A for some children and should not be regarded as suitable until a test has been made on the individual concerned. The supplement they advise consists of balanced calories and mineral salts, with a smaller amount of vitamins than is commonly recommended nowadays. During the experiment eight children contracted measles, four on the basal diet and four on the diets containing supplements; it is suggested that these figures may be a sign that resistance to infection was conferred by the supplements. The data, however, are too few to bear this out, while the high incidence of measles on children of all social classes when exposed to risk does not support the idea that resistance is readily increased by extra feeding. Broadly, this carefully planned experiment indicates that the basic diet of the children involved was little more than sufficient to meet their maintenance requirements, so that the additional 74 calories provided daily—though small compared with the total calorie intake—was of importance for growth. If the experimental and administrative difficulties are not insuperable it would be useful to have similar data from larger numbers of children kept on the different diets for rather longer periods.

MALIGNANT TUMOURS OF BONE

The ultimate results of radical excision for osteogenic sarcoma of an adolescent bone make a sad tale, and even when surgery is backed up by vigorous pre-operative irradiation of the primary site and post-operative deep X ray therapy of the lungs, the number alive at the end of five years is tragically small. The obvious remedy—which amounts to a pressing necessity—is earlier diagnosis, for which Mr. Harry Platt, in his Lady Jones lecture,[1] makes a strong appeal, based on the solid fact that pain is almost invariably experienced before a tumour is appreciable, and although intermittent at first becomes severe and continuous as the tension in the periosteum increases. As three-quarters of these growths are in the neighbourhood of the knee, persistent pain in this region in a healthy adolescent or young adult calls for careful clinical and radiological investigation, with the possibility strongly in view that its cause may be a primary osteogenic sarcoma. Unfortunately at the stage when these growths offer a fair prospect of permanent cure their radiological appearance is far from pathognomonic and their diagnosis likely to present a clinical problem of such difficulty that the advisability of biopsy has to be considered. Mr. Platt, while opposed to the indiscriminate performance of biopsy—it should, he thinks, be used as a last resort and with great precaution—has found it a valuable aid in the diagnosis of early tumours in which the clinical and radiological findings are atypical. He advocates removal of the material under a tourniquet and its examination by a pathologist "continuously engaged in the study of the bone tumour problem," for he regards as a waste of time the occasional submission of material to a pathologist who is sceptical of the value of the method. The discovery of pulmonary metastases whilst the primary tumour is still quite small is happily very rare. Mr. Platt pays tribute to the success which has followed the mass attack on primary bone sarcoma in the United States of America.[2] The latest report of the American "bone sarcoma registry" contains records of 74 five-year cures of osteogenic sarcoma in a total of 504 registered cases. Early diagnosis and prompt surgical measures probably take the predominant share in producing these very encouraging figures, but an analysis of the figures suggests that Coley's fluid must be regarded as a potent agent. The results justify an experimental inquiry into the retarding action which these bacterial toxins exert on sarcomata. The results of irradiation alone in the treatment of bone sarcomata are disappointing. Mr. Platt gives a concise account of Ewing's tumour of bone, but does not refer to the work of Oberling,[3] who has made a good case for regarding these tumours as of reticulo-endothelial origin. In describing the secondary malignant tumours of bone, he points out that when a malignant adenoma of the thyroid or a hypernephroma of the kidney has been found associated with a solitary bony metastasis, both primary and secondary growths have occasionally been successfully excised.

PROF. BRERETON BAKER

The death last Saturday of Herbert Brereton Baker at his home at Gerrards Cross will leave a gap in many friendships. In the chair of chemistry at the Imperial College for 20 years he moulded the approach of innumerable science students to chemical problems, and no student escaped without the impress of his teaching, for Baker was a disciplinarian of the first order. He had had experience of less serious teaching material as science master at Dulwich College and headmaster of Alleyn's School, the lower school of the College, before he came to South Kensington. But just as much a part of his life was the urge to investigate the properties of gases, a research begun in his early days as assistant to H. B. Dixon at Oxford, and broken only during the war when he was called on to counter the unexpected and terrible dangers of gas attack. There is a current story, probably apocryphal, that he was unwilling to part to anyone with the secret of an ineffably fatal gas of his own. After the war Baker returned again with great content to the extraordinary discovery he had made earlier with Dixon that gases like hydrogen and oxygen can scarcely be induced to combine without the presence of traces of moisture; the interval had indeed served him in good stead, for it allowed some of his gaseous mixtures to undergo a year-long desiccation and to reach a state aptly known at South Kensington as "Bakerian dryness." At home he had the relaxation of profound absorption in fishing and other country pursuits, and the abiding joy of a wife who shared with him the interests of his scientific work.

VACCINATION AGAINST TYPHUS

The March *Bulletin* of the International Office of Public Health contains two interesting communications on different methods of vaccination against typhus exanthematicus fever which is prevalent in certain parts of North Africa. The first paper, which was communicated by Dr. Gaud, the delegate for Morocco, deals with the method originated by Dr. Georges Blanc, director of the Institut Pasteur of Morocco, and described by him in communications to the Académie de Médecine on Oct. 31st, 1933, and May 1st, 1934. In these Blanc had shown that the virus of murine typhus isolated from Casablanca rats immunised guinea-pigs not only against murine typhus, but also against classical typhus. As the result of further experiments he found that murine typhus virus, which from the first is only feebly pathogenic for man, can be rendered absolutely non-pathogenic by the addition of bile. The present communication relates the results of an investigation carried out by Blanc in conjunction with Gaud on 723 inmates of a penitentiary, aged from 16 to 60, 309 of whom were injected intramuscularly with 1 c.cm. of the vaccine in a dilution of 1 in 1000 and 414 with 2 c.cm. of the same vaccine in a dilution of 1 in 500. A febrile reaction lasting 4–9 days occurred in 1·6 per cent. of the first group and in 4 per cent. of the second. Revaccination of 75 persons with 1 c.cm. of a dilution of 1 in 1000 three weeks after the first inoculation was followed by no reaction. Tests were then made on five revaccinated persons, and it was found that whereas control subjects inoculated with murine typhus reacted in the same way as control guinea-pigs, the inoculated individuals showed no reaction at all; thus indicating that they were absolutely immune. The future will show the duration of the immunity conferred by this method. In the meantime Gaud regards it as at once practical, harmless, and efficacious. The second communication, which was made by Dr. Mohammed Shahin Pasha, the Egyptian delegate, gives a brief account of the uses of Weigl's method of antityphus vaccination which was carried out on 183 persons in an Egyptian village where typhus had been rife during the last two years. Three injections were given and in some cases were followed by a mild reaction. Only one of those inoculated subsequently contracted typhus. The village will be kept under observation for some time in order to determine the duration of the immunity conferred by the vaccine.

GRAPHIC RECORDS

PICTORIAL representation of the progress and results of experimental investigations in pathology has long been recognised as a convenient and time-saving method of keeping records. Those familiar with the Scientific Reports issued from time to time by the Imperial Cancer Research Fund will recall the black silhouettes showing alterations in size and shape of induced neoplasms, the wedges which are used to indicate progressive growth, and the symbol of death (†) which, incidentally, is the accepted formula introducing obituary notices in many foreign journals. An effective example of the graphic method of representation as applied to records of human disease is supplied by the group of surgeons attached to St. Thomas's Hospital who combine in a contribution to our Prognosis series this week (see p. 1059). The method was instituted some years ago by Sir Cuthbert Wallace as an easy way of keeping follow-up records and of enabling after-results to be seen at a glance; by its use statistics of a large number of consecutive cases of various surgical conditions are being accumulated in accessible form. The 149 consecutive cases of carcinoma of the stomach which form the basis of the present article are divided into inoperable and operable cases, and the length of history, type of intervention, and subsequent duration of life are graphically recorded by a skilful combination of lines and dots. The original charts, reduced in size for reproduction, are made on squared paper with 12 divisions to the inch, so that on the convenient scale of an inch to a year records can be kept in months. It might be objected that such a pictorial record is necessarily incomplete. For example, the fact that the subjects of carcinoma of the stomach on whom it was possible to perform a partial gastrectomy lived nearly four times as long, on the average, as those with inoperable growth means little without the supplementary information, supplied in the text, that their discomfort was also greatly lessened. But the need for additional notes is implicit in any graphic representation which is not overweighted by so many signs and symbols as to lose its simplicity. Nearly everyone carries away a more deep and lasting impression from the contemplation of a picture than from study of a table of figures, and authors who believe that the statistics they have collected carry a cogent message are well advised to present them in diagrammatic form.

DEATH AND THE DOCTOR

DURING 1934 the *Journal* of the American Medical Association published the obituaries of 3231 physicians of the United States, and in its issue of April 6th these notices are subjected to a cold and impersonal statistical analysis. The average age at death was found to be 64·3 years, a figure that compares closely (as far as calculation is possible) with the age that can be computed for English medical practitioners from the Registrar-General's 1921–23 report on occupational mortality. In the States heart disease was the leading cause of death, followed, in order, by cerebral hæmorrhage, pneumonia, and cancer. Deaths from violence —accidents, suicides, and homicides—appear high, amounting to nearly 7 per cent. of the total, but no standard of comparison with other occupations is given and alone the figures are not very informative. A relatively high rate from violence would certainly be in accordance with the 1921–23 experience of England and Wales, for the Registrar-General's report shows an accident-rate more than double that of the other occupations of social Class I., and a suicide-rate double that of all occupied and retired males—though this latter high rate is shared by other occupations of social Class I. Taken as a whole, however, the *mortality of medical practitioners* in this country does not differ from the general average appreciably at any time of life. Acute non-tuberculous respiratory diseases, influenza, and pneumonia seem to be a special risk, but the phthisis mortality is low. The English and American figures appear generally to be in accordance though no close statistical comparison is possible. Considering the obvious facilities for adequate and systematic treatment, it is somewhat interesting to observe eleven American physicians recorded as dying of pernicious anæmia. This is a case in which the physician might well be expected to heal himself; perhaps the explanation lies in the certification and tabulation of death in which he could hardly be expected to assist.

ENGLISH PRISONS IN 1933

WHILE the health of our prison population continues to reflect great credit upon our medical officers of prisons, the latest annual report of the Commissioners of Prisons, dealing with the year 1933 (Cmd. 4872. 1*s.* 6*d.*), indicates that improvements in our administration of justice are still possible. The Medical Commissioner has repeatedly complained of the way in which courts of summary jurisdiction deal with mentally affected prisoners. There has been an unhappy tendency for magistrates to sentence to imprisonment a man whom they believe to be mentally defective or insane. Sometimes too they have asked the prison authorities to keep a man under observation during sentence so that the court may be informed of his mental condition prior to release. This information seems to be asked for with a view to dealing with the prisoner on some future reappearance by which time it may be valueless and misleading. In any event the practice is improper, since prison officers are not authorised to submit reports on the state of mind of convicted persons to anybody but the prison authorities. A third point is that medical officers, when asked to report on an accused person's mental condition, are not given such full material as to the facts and the medical history as they are entitled to have. The Home Office apparently drew the attention of magisterial courts to these three points during 1934. It is disquieting to find that cases still occur where offenders are convicted and sent to prison in spite of the fact that medical reports are before the magistrates which state that the men are certifiable under the Lunacy or Mental Deficiency Acts. There is no legal power at present to compel a defendant, when remanded on bail, to attend and undergo medical examination at a clinic or elsewhere in order that his state of mind may be examined. This gap in the law seems worth filling.

As regards women prisoners, the medical officer of Holloway Prison comments on the reception of a fresh type of prisoner—namely, girls under 21, sentenced to 7 or 14 days' imprisonment, who have been suffering from syphilis and gonorrhœa. He describes them as of low mentality, and observes that the shortness of the sentence gives no time to treat their physical, or investigate their mental, condition. They receive treatment while in prison but they return to the streets of some seaport town in an infectious state. The medical officer boldly suggests that, in spite of legal ideas of the liberty of the subject, the magistrates should be empowered to pass a sentence of such length as will give a reasonable chance that the woman's disease will be controlled if not cured—and this will mean many months.

The Medical Commissioner acknowledges the help of the civil hospitals where 156 prisoners and Borstal inmates were temporarily treated during 1933. A few abscond, of course, and the civil hospitals naturally are not enthusiastic about admitting convicts to a general ward; some prisoners, too, feign illness or produce conditions which require operative treatment in order to obtain the greater comfort of a civil hospital. For these reasons, he says, arrangements are being made for an operation theatre in a prison in the London area. Major operations are carried out in five provincial prisons with great advantage.

Since the last report was issued a medical psychologist has been attached for duty at Wormwood Scrubs. The present report warns us not to expect any early conclusions as to the value of psychotherapy in delinquent cases. The medical officer at Maidstone Prison has made a few attempts at psychotherapeutic treatment, but he records that in only a few cases was real coöperation obtained. He adds a cheerful story of one prisoner who wanted his dreams analysed. At the first interview it was found that what the man really wanted was a softer mattress, because a hard bed made him dream so much. The interviews were, by mutual agreement, discontinued.

WAR IN THE CHACO

THE war between Bolivia and Paraguay has been fought in (and over) a country that is barely habitable. Descriptions such as Duguid's "Green Hell" some years ago familiarised many of us with its uninviting characteristics, and from Dr. J. W. Lindsay we now have a report[1] which brings out the unusual nature of the medical problems that have arisen there. Dr. Lindsay has long been honorary medical officer to the Protestant Missions in Paraguay, and he tells us that the efficient medical services of the country sufficed in peace-time to cope with incipient outbreaks of disease; in fact, the fundamental disadvantages of the area are extremes of drought and damp rather than endemic infections. But the throwing of large masses of men into a roadless and often waterless country broke down the sanitary arrangements for the first six months of the war, and severe outbreaks of enteric, ankylostomiasis, malaria, and vitamin-deficiency diseases followed. The enteric was found to be due to a paratyphoid bacillus, *Salmonella paratyphus* Chaco, and has been largely controlled by a specific vaccine; hookworm anæmia has been dealt with by the issue of boots; the malaria was very benign, and a dry season has greatly reduced its incidence; while improved transport, allowing of proper rations, particularly of the yerba maté, has controlled the avitaminosis. Of maté, which has recently been shown to be rich in vitamins A and B and whose virtues have long been preached by travellers returning from South America, Dr. Lindsay states that it "makes the most wonderfully stimulating and sustaining army ration ever produced." The Bolivian prisoners were always found with a ration of coca leaves, and it is suggested that their lack of fighting spirit was due as much to the coca as to the character of the country which was so strange to them. The immense distances have made the transport difficulties colossal. At one time the Bolivian capital was 1535 miles from the front, of which about 1000 miles had to be on foot. The Paraguayans had 300 miles by steamer from Asunçion, then 100 miles of light railway, and 600 miles of marching. Bullock carts were at first the only means of transport for the wounded, but now improved roads and motor lorries are available, while air transport is used for serious cases, a journey formerly taking 2–3 weeks by bullock cart taking 2–3 hours by air. When Dr. Lindsay wrote, conditions had settled down, and a good bill of health was reported both in the Army and in Paraguay as a whole. Foreign medical officers, with the exception of Major Arthur Weiss, the Russian director of the Paraguayan Army Prophylaxis Corps, have now "faded out," and Paraguayan medical officers take service with the Army for six-monthly periods, continuing their civil practice in the intervals.

One enemy which the Paraguayans have quite failed to conquer is the flies. "In the hospitals flies were all over the dead and dying. In the field one would see half a dozen heaps of black, and they were found to be dead bodies buried in flies."

OF HEALTH RESORTS

LAST week saw the opening of new baths at Woodhall Spa and of a new clinic for the treatment of rheumatism at Buxton. Details of the latter function are given this week in connexion with a report of the simultaneous meeting at Buxton of the British Health Resorts Association. The proceedings at both spas were similar in respect of the things that were said at the meetings, the unanimous opinion being expressed that the spa and the health resort were now proving themselves essential to any national scheme for the promotion of physical well-being. At Buxton the suggestion was made that centres for health and recreation at suitable places, whether inland or on the coast, should be established not necessarily directed only to the treatment of particular diseases or to the reception of various classes of patients, but prepared to receive a general public seeking what they could offer. The idea has much force. Our younger population, especially the urban among them, to-day gain improved physical health and pleasant change of environment by hiking in company, and a scheme that would provide these gay and sensible bands with centres at which meetings among themselves could be held has much to commend it, for the modern tramps by force of numbers and coöperation would obtain the necessary amenities. And they would thus supply a practical argument for the brightening of the social life at our existing spas. At the Buxton meeting this came in for comments of a severe character; and though the speakers framed their criticisms with a spirit of levity, in their joking they were very serious. What Sir Landon Ronald said of the artistic appreciation displayed by spa authorities with regard to music was completely scathing although so urbane, while Mr. St. John Ervine described their dramatic taste in terms of devastating drollery. They succeeded in convincing their audience that spa authorities would have to consider the position, for though the dullness of the British health resort has met with frequent denunciation, it has never before been so cruelly and aptly expressed. It seems clear that the time-honoured plea of the rigour and caprice of the British climate will not suffice as an answer to those who ask that some mental food and relaxation should be offered to spa patients, and especially to their accompanying friends, who outnumber them. At all our health resorts the accommodation has vastly improved and is still improving, while the medical science displayed at them is now of a high order and the practical adjuncts to treatment, often very costly, are supplied in immediate response to medical requisition. The patient is placed in the most pleasing surroundings possible and his medical care is sound and scientifically applied. It is administered by physicians and surgeons who not only have the special skill and experience necessary, but who are stimulated by real enthusiasm for practice along their special line. These are great things; they are indeed the greatest things; but the fact remains that the social life of the spa is grey. Better music and better dramatic entertainment during the seasonal periods would work a real change.

DISTRESS AND HEALTH

LAST December Dr. G. F. Walker wrote a letter to the *Times* declaring that in the district where he works, "between the Tyne and the Tees," there is a substantial and progressive deterioration in public health. This deterioration, he said, is taking place despite "resolute, competent, and generous local efforts," and he wanted to combat the tendency towards complacency in national feeling about the distressed areas. His general conclusion so far conflicted with the opinions expressed in Sir George Newman's annual reports that the Ministry of Health immediately instructed Dr. James Pearse, Dr. J. Alison Glover, and Mr. F. W. Grant to investigate the state of affairs thus represented. The results of their inquiry in Sunderland and its neighbourhood [1] give no grounds for the complacency which Dr. Walker deplores, but neither do they justify his belief in a serious and progressive decline. The investigators think that he "has been misled by his professional contact with the sick into drawing conclusions which he applies generally to a wide population, and that he has limned a medical picture in unduly dark lines to correspond with the economic background of a depressed area." If his object was to emphasise that the burden of combating disease is more than this area can bear, this object may have been legitimate; but they regard the medical basis of his arguments as unsound. In particular, Dr. Walker maintained that children and young adults are nowadays more prone to infections and catarrh; that anæmia of malnutrition is increasing; that conditions in the district make chorea and rheumatism endemic; that neurotic maladies are distressingly common; that rickets is highly prevalent; and that conditions of bodily dilapidation are causing a startling increase of metabolic diseases such as diabetes and pernicious anæmia; while "thousands and thousands of poor people in this area labour under disabilities such as pyorrhœa, deafness, gastritis, sciatica, bronchitis and sinusitis." Dr. Pearse and Dr. Glover, however, find that the general death-rate, the infant mortality-rate, the death-rate from bronchitis and pneumonia, and the case-mortality of scarlet fever and diphtheria do not indicate unfavourable effects from the present economic conditions. Tuberculous infection is still much in evidence, but except in the age-group 15–24 (which tends to be disturbing throughout the country) there is no sign that the long-continued unemployment has done more than retard the rate of improvement. Clinical examination has shown minor manifestations of rickets in 4·5 per cent. of young children seen at welfare centres, but the disease has much diminished in prevalence, and gross rickets is rare; "no other deficiency diseases have appeared." Clinical examination of persons in various categories suggests that about three-quarters have a good standard of health, the condition of adolescent youths being the least satisfactory. There is some prevalence of anæmia but it does not seem to be rapidly increasing; there is little reason to think that catarrh is commoner; and though there may be more neurotic maladies, Dr. Pearse and his colleagues are impressed rather with the courage with which difficulties are faced. The slightly higher incidence of acute rheumatism and chorea in the area is probably associated epidemiologically with the recent prevalence of scarlet fever, and is general in the county. Of the minor disabilities mentioned by Dr. Walker, pyorrhœa is notably common, and also perhaps gastritis; but there is no sign of increase in diabetes or pernicious anæmia. Though Dr. Walker's views are supported by some members of the medical profession in Sunderland and the adjacent districts (one of their letters is quoted at length), his colleagues on the whole disagree with what he says—except perhaps about the degradation in temperament of young men. Practitioners of wide experience have said that conditions are better than formerly owing to the operation of the public health services, and readers of this illuminating report must be thankful for the existence of these antidotes to some of the poisons attacking our social system.

THE governors of St. Bartholomew's Hospital have accepted a tender for the erection of a block of buildings to provide accommodation for 250 medical beds. Building operations will begin at once, and the work is to be completed in a year and a half. The new medical block will be known as King George V. Building. It is hoped that the private Bill now before Parliament will enable some of the accommodation to be used for the benefit of middle-class persons.

PROGNOSIS

A Series of Signed Articles contributed by invitation

L.—PROGNOSIS OF CARCINOMA OF THE STOMACH

This article is based on 149 consecutive cases of carcinoma of the stomach admitted to St. Thomas's Hospital under one firm during the 13 years, 1920–1932, under the care of one or other of us.

The few cases operated on during this period for chronic ulcer, in which microscopy suggested small areas of so-called malignant change, are not included in this series. Prognosis in such cases has been found by us to be invariably good, as contrasted with primary and undoubted carcinoma; we do not believe that such cases are, in fact, malignant.

The accompanying charts are self-explanatory. This particular method of recording a graphic representation was instituted by one of us (C. S. W.) as affording an easy method of keeping the "follow-up" records up to date, and of enabling the after-results to be seen at a glance.

In the two charts each horizontal line represents one case; the dark vertical line the date of operation, or of admission if no operation was performed; to the left and right of this line are shown the duration of the history and duration of life after operation respectively, each large division representing a year and each small division three months.

The total of 149 cases has been divided into two groups; the inoperable, in which excision was not possible, are shown in Chart I, and the operable, in which a partial gastrectomy was performed, in Chart II.

INOPERABLE CASES

The 122 *inoperable* cases are shown in Chart I. Of these, 1 was untraced; only 9 lived for a year or more after operation, but 1 lived for 3 years and 1 month. Excluding the case not traced, the average duration of life of the remaining 121 cases works out at 3·3 *months.* If the 17 patients who died within one month (all of these were operated on) are excluded, the average duration of life of the remaining 104 cases works out at 4·0 *months.*

It may be noted in passing that these 104 cases were made up of (*a*) 70 patients upon whom a short-circuiting operation, or one enabling food to be taken, was performed—that is to say, gastrojejunostomy 56 cases, gastrostomy 13 cases, jejunostomy 1 case; and (*b*) 34 patients upon whom either a laparotomy only was performed—26 in all, or no operation was performed—8 in all. The expectation of life in the former group of 70 cases was 6 months, and although a gastrojejunostomy relieved pyloric stenosis as such, it did nothing to relieve the gastritis which is associated with carcinoma of the stomach, and is a principal agent producing symptoms. Attempts to relieve gastritis by therapeutic measures proved extremely disappointing.

OPERABLE CASES

The 27 *operable* cases are shown in Chart II. One lived for 6 years and 3 months (carcinoma proved microscopically). The average duration of life works out at 12·3 *months*—i.e., nearly four times as long as the average in the inoperable group. If the 9 patients who died within one month of the operation are excluded, the average duration of life of the remaining 18 cases works out at 18·5 *months.* Assuming that all deaths occurring within one month of the operation are due directly, or indirectly, to the operation, the

CHART I

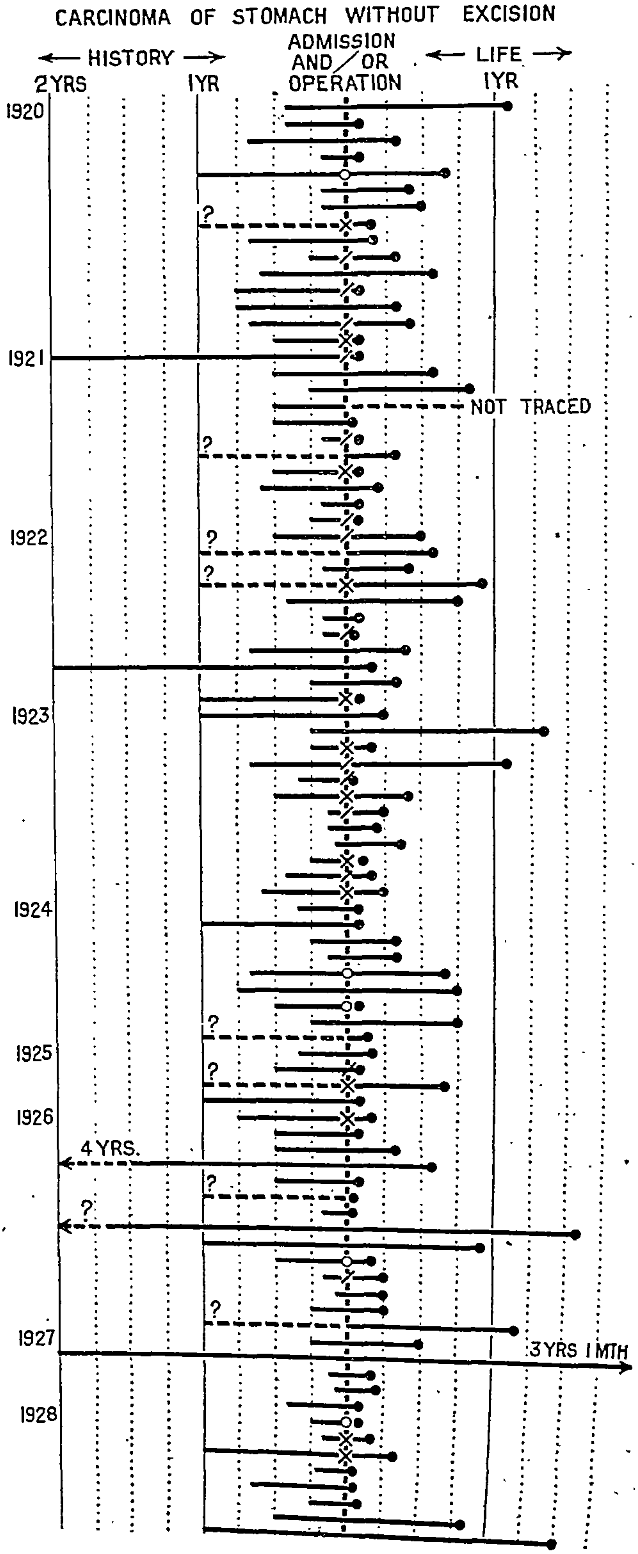

CHART I

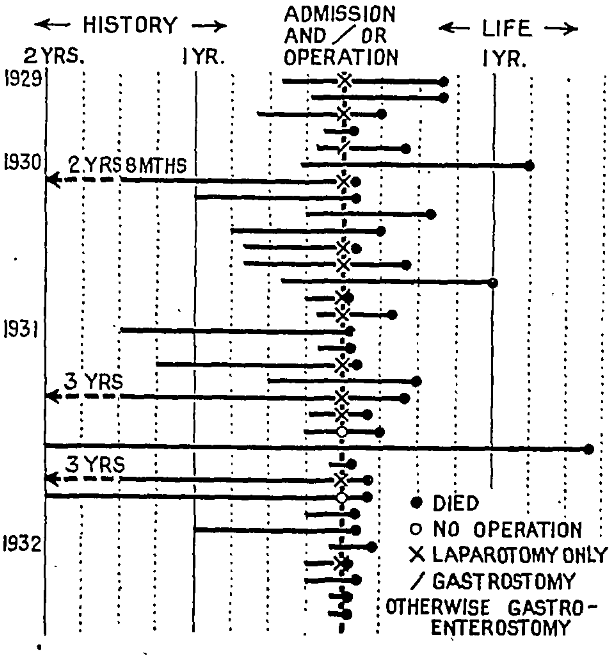
(*continued*)



operative mortality works out at 33·3 per cent. The causes of these 9 deaths were as follows: shock 2, peritonitis 1, duodenal fistula and peritonitis 1, pulmonary thrombosis 1, broncho-pneumonia 2, exhaustion and cardiac failure 2.

Although not quite within the scope of this paper, it is of interest to note that the average length of history in the inoperable group (excluding 9 cases, duration unknown) was 7·1 months (Chart I), while that in the operable group (excluding 1 case, duration unknown) was 5·5 months (Chart II). The short history in almost all these cases of carcinoma of the stomach contrasts with the long history in almost all cases of chronic ulcer, and is a strong argument against the view that carcinoma commonly starts in a chronic ulcer.

While it is generally recognised that the results after partial gastrectomy for carcinoma of the stomach are bad, and those after some palliative operation are worse, the mere statistical data do not give a picture of the relief of suffering obtained by the radical operation, for from personal observation there is no doubt that the remaining months of life are far less distressing for a patient who has had a partial gastrectomy than for one who has not.

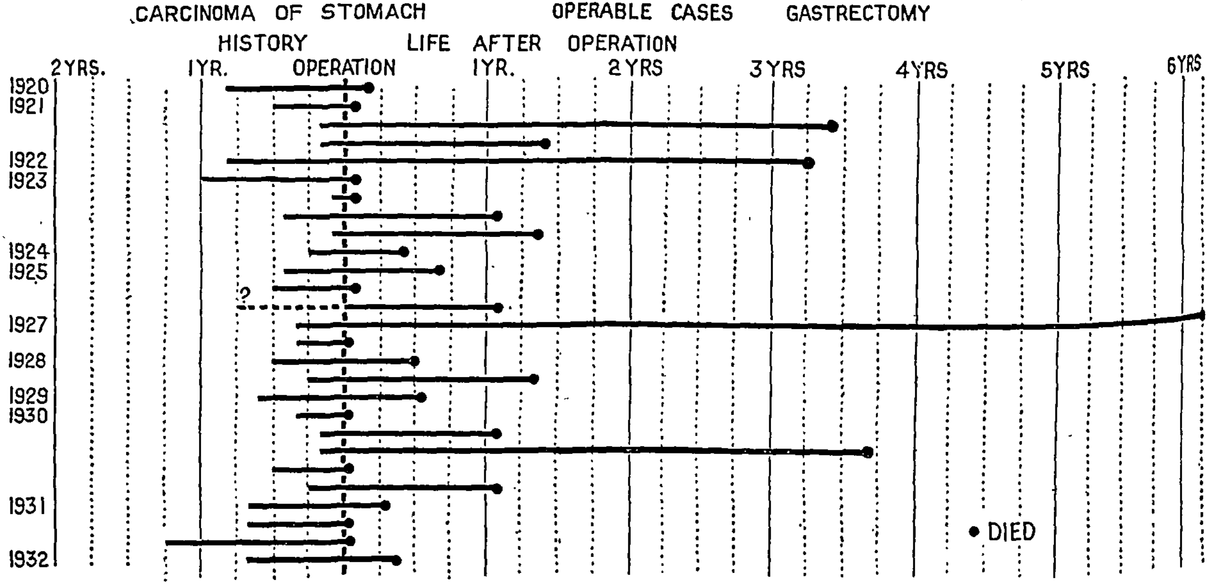
CHART II



Britsh Association of Radiologists.—During the past year a new radiological society, bearing this title, has been formed. The objects of the association are the advancement of medical radiology in all its branches, with particular reference to its clinical, ethical, educational, and economic aspects. An annual meeting or congress will be held at a selected centre, at which members from all over the country may meet and obtain first-hand knowledge of work as it is going on in other centres. The first annual meeting will be held at Birmingham in June this year, and will extend over two days. The programme will follow the precedent of such occasions and will include a presidential address, hospital visits, and exhibition and demonstration of radiograms of various conditions, and an annual dinner. The date of the meeting and the details of the programme will be announced shortly. The Association has been formed with an initial membership of about one hundred, and Dr. James F. Brailsford is the first president. Membership is limited to registered medical practitioners who have been engaged solely in the practice of radiology, or radiology and therapeutics, for at least five years. Those who have been in practice for a shorter period are eligible as associate members until they qualify as full members. Elections to the Association will be made at the annual general meeting on the nomination of the council, and those elected will be entitled to attend the subsequent functions of the congress. Proposal forms for membership may be obtained from the Hon. Secretary, Dr. S. C. Shanks, 68, Harley-street, London, W.1.

SPECIAL ARTICLES

THE BRITISH HEALTH RESORTS ASSOCIATION:

THE NEW BUXTON CLINIC

A NEW clinic at Buxton for the treatment of rheumatic diseases was declared open on Friday, April 26th, by Lord Horder. Members of the British Health Resorts Association held at the same time a conference at Buxton. The Duke of Devonshire presided over the opening ceremony and briefly indicated the long interest of his family in the Buxton spa, adding personal testimony to the benefits received from the Buxton treatment.

Lord Horder said that he would be deliberately brief as the company were to inspect the new clinic at the close of the talking. The particular duty before them to-day was to see the new clinic for rheumatic diseases by which valuable and appropriate treatment could be provided for those whose social status made them ineligible as charges of voluntary hospitals. Of the Royal Devonshire Hospital at Buxton he said that it was actually the oldest institution in the country which had devoted research to rheumatic disorders, and now, with the establishment of the new clinic, efforts were being made to advance pathological investigations, assisted by the most modern equipment. He spoke warmly of the team-work done by Buxton doctors; as clinicians and orthopædists, pathologists, biochemists, and physicists their services were available, and he proclaimed his personal enthusiasm about the future of the clinic. Alluding to the modest prices which would be charged, he said that as an advocate of the paying beds system he had always held that there should be facilities afforded to the patient of moderate means. That this would be so at the Buxton clinic gave special pleasure to his duty in declaring the institution open.

The clinic was then open for inspection. It is situated at one end of the famous Buxton crescent, receives 100 patients, and contains every convenience of a modern hospital—careful lighting, central heating, and ample hot and cold water-supply in the separate rooms. The general accommodation includes a reception-room, lounges for men and women, and consulting-rooms for doctors. There is provision for the developing of X ray photographs, while arrangements have been made with the authorities of the Royal Devonshire Hospital for the services of their bacteriological and biochemical departments. The clinic is in direct proximity to the baths which can be reached under cover, the patients virtually residing in the same building. These, with their range of swimming pools through which water continually flows at its natural temperature of 82°, are admirably designed, and the arrangements for packs and colloidal heat baths, for colon lavage, and for manipulative douching, where the massage of the patient is undertaken under thermal water, are complete.

In the evening the Mayor of Buxton, Councillor W. R. Sanders, J.P., presided over a dinner at St. Anne's Hotel, when the corporation welcomed their guests. After the loyal toasts the Duke of Devonshire proposed Lord Horder's health saying that Lord Horder had been a good friend to Buxton already and was giving further proof of his regard for the spa by opening the new clinic that afternoon. Anything, said the Duke, that would relieve the human race of the scourges of gout and rheumatism was welcome to-day, and he concluded by making some pertinent remarks on the amenities of spa life, referring to that "greatest nuisance of the post-Victorian era, the noise of the motor-car." Lord Horder, in reply, gave some humorous details of the charges that were wont to be paid at the Buxton spa some 400 years ago, when the weekly rates for visitors had been fixed as follows: dukes, £3 10*s.*, that being exactly the charge for the cheapest bed in the new clinic; earls, 10*s.*; doctors, 10*s.*; gentlemen. 3*s.*; yeomen, 1*s.* Lord Horder thought that as half the money paid went to the doctors they got a good rebate on the charges. He quoted a letter addressed to the director of the baths by Queen Elizabeth as showing that Her Majesty possessed a pretty wit. The Earl of Leicester was undergoing a treatment and the Queen wrote as follows:—

> "We think it meet for the saving of our credit to prescribe unto you a proportion of diet which in no case you shall exceed, and that is to allow him (Lord Leicester) by the day of his meat two ounces of flesh, referring the quality to yourselves so as you do not exceed the quantity, and for drink one-twentieth of a pint of wine to comfort his stomach and as much of St. Anne's sacred water as he lusteth to drink. On Festival days, as is fit for a man of his quality, we can be content you shall enlarge his diet by allowing him for his dinner the shoulder of a wren, and for his supper a leg of the same beside his ordinary ounces. The like proportion we mean you shall allow unto our brother of Warwick, saying that we think it meet in respect that his body is more replete than his brother's, that the wren's leg allowed at supper be abated."

He concluded by speaking of the value to the patient provided by the ideal surroundings of Buxton, the pure tonic air and beneficial effects of the thermal waters, an environment admirably supplemented by the up-to-date methods of treatment which now prevailed under the careful and accurate diagnosis of the spa doctors. Sir Squire Sprigge proposed the toast of prosperity to the B.H.R. Association, whose function he said was to collect information about the health resorts to be made available for doctors and their patients. While allowing the natural advantages to be derived in certain circumstances at many well-known continental spas, he said that to seek medical assistance abroad led to a lamentable break in treatment and both this break and the expense could often be avoided if the patient and the doctor knew that treatment similarly appropriate could often be obtained in the British Isles whose varieties of climate and physical geography were so remarkable. The toast was responded to by Dr. W. G. Willoughby, M.O.H., Eastbourne, who called the attention of the company to the diffusion of accurate information in the guide-book of the Association edited by Dr. Fortescue Fox, which now dealt faithfully with the claims made by various centres. The Association, he said, should be duly grateful to the publicity which the press now gave to its efforts, and of the secretary of the Association, Dr. Alfred Cox, he said that he was indefatigable and imperturbable. Dr. Kaye le Fleming, proposing the toast of prosperity to Buxton, said that the town and spa were representing the keenness of the day for the promotion of physical culture. He considered this a very live question, and asked if he was looking too far ahead when he visualised the establishment of health resorts which would cater for a large section of the public—health resorts which would provide something more than treatment for the sick, but baths, gymnasia, and playing grounds for the well. The toast was replied to by the Mayor of Buxton, who pointed out that Buxton possessed many of the necessary amenities, such as beautiful gardens and

CHART I

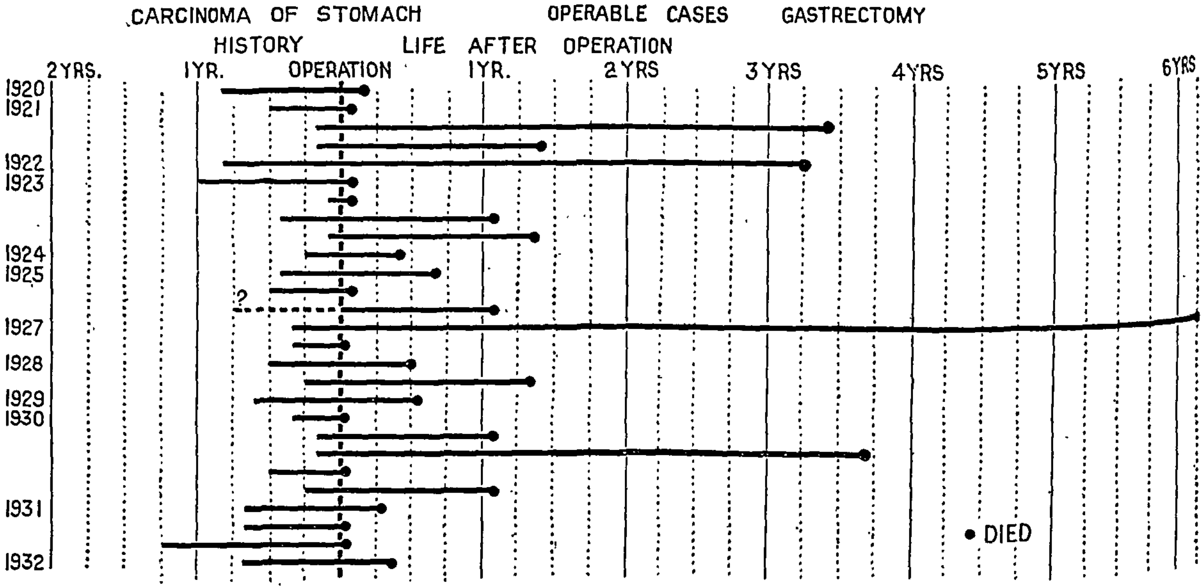
CHART II



BRITISH ASSOCIATION OF RADIOLOGISTS.—During the past year a new radiological society, bearing this title, has been formed. The objects of the association are the advancement of medical radiology in all its branches, with particular reference to its clinical, ethical, educational, and economic aspects. An annual meeting or congress will be held at a selected centre, at which members from all over the country may meet and obtain first-hand knowledge of work as it is going on in other centres. The first annual meeting will be held at Birmingham in June this year, and will extend over two days. The programme will follow the precedent of such occasions and will include a presidential address, hospital visits, and exhibition and demonstration of radiograms of various conditions, and an annual dinner. The date of the meeting and the details of the programme will be announced shortly. The Association has been formed with an initial membership of about one hundred, and Dr. James F. Brailsford is the first president. Membership is limited to registered medical practitioners who have been engaged solely in the practice of radiology, or radiology and therapeutics, for at least five years. Those who have been in practice for a shorter period are eligible as associate members until they qualify as full members. Elections to the Association will be made at the annual general meeting on the nomination of the council, and those elected will be entitled to attend the subsequent functions of the congress. Proposal forms for membership may be obtained from the Hon. Secretary, Dr. S. C. Shanks, 68, Harley-street, London, W.1.

SPECIAL ARTICLES

THE BRITISH HEALTH RESORTS ASSOCIATION:

THE NEW BUXTON CLINIC

A NEW clinic at Buxton for the treatment of heumatic diseases was declared open on Friday, April 26th, by Lord Horder. Members of the British Health Resorts Association held at the same time a onference at Buxton. The Duke of Devonshire preided over the opening ceremony and briefly indicated he long interest of his family in the Buxton spa, dding personal testimony to the benefits received rom the Buxton treatment.

Lord Horder said that he would be deliberately brief s the company were to inspect the new clinic at the lose of the talking. The particular duty before them o-day was to see the new clinic for rheumatic diseases y which valuable and appropriate treatment could be rovided for those whose social status made them ineligible s charges of voluntary hospitals. Of the Royal Devonhire Hospital at Buxton he said that it was actually the ldest institution in the country which had devoted esearch to rheumatic disorders, and now, with the estabishment of the new clinic, efforts were being made to dvance pathological investigations, assisted by the most nodern equipment. He spoke warmly of the team-work lone by Buxton doctors; as clinicians and orthopædists, athologists, biochemists, and physicists their services vere available, and he proclaimed his personal enthusiasm bout the future of the clinic. Alluding to the modest rices which would be charged, he said that as an advocate f the paying beds system he had always held that there hould be facilities afforded to the patient of moderate neans. That this would be so at the Buxton clinic ave special pleasure to his duty in declaring the instiution open.

The clinic was then open for inspection. It is situated at one end of the famous Buxton crescent, receives 100 patients, and contains every convenience of a modern hospital—careful lighting, central heating, and ample hot and cold water-supply in the separate rooms. The general accommodation includes a reception-room, lounges for men and women, and consulting-rooms for doctors. There is provision for the developing of X ray photographs, while arrangements have been made with the authorities of the Royal Devonshire Hospital for the services of their bacteriological and biochemical departments. The clinic is in direct proximity to the baths which can be reached under cover, the patients virtually residing in the same building. These, with their range of swimming pools through which water continually flows at its natural temperature of 82°, are admirably designed, and the arrangements for packs and colloidal heat baths, for colon lavage, and for manipulative douching, where the massage of the patient is undertaken under thermal water, are complete.

In the evening the Mayor of Buxton, Councillor W. R. Sanders, J.P., presided over a dinner at St. Anne's Hotel, when the corporation welcomed their guests. After the loyal toasts the Duke of Devonshire proposed Lord Horder's health saying that Lord Horder had been a good friend to Buxton already and was giving further proof of his regard for the spa by opening the new clinic that afternoon. Anything, said the Duke, that would relieve the human race of the scourges of gout and rheumatism was welcome to-day, and he concluded by making some pertinent remarks on the amenities of spa life, referring to that "greatest nuisance of the post-Victorian era, the noise of the motor-car." Lord Horder, in reply, gave some humorous details of the charges that were wont to be paid at the Buxton spa some 400 years ago, when the weekly rates for visitors had been fixed as follows: dukes, £3 10*s.*, that being exactly the charge for the cheapest bed in the new clinic; earls, 10*s.*; doctors, 10*s.*; gentlemen, 3*s.*; yeomen, 1*s.* Lord Horder thought that as half the money paid went to the doctors they got a good rebate on the charges. He quoted a letter addressed to the director of the baths by Queen Elizabeth as showing that Her Majesty possessed a pretty wit. The Earl of Leicester was undergoing a treatment and the Queen wrote as follows:—

> "We think it meet for the saving of our credit to prescribe unto you a proportion of diet which in no case you shall exceed, and that is to allow him (Lord Leicester) by the day of his meat two ounces of flesh, referring the quality to yourselves so as you do not exceed the quantity, and for drink one-twentieth of a pint of wine to comfort his stomach and as much of St. Anne's sacred water as he lusteth to drink. On Festival days, as is fit for a man of his quality, we can be content you shall enlarge his diet by allowing him for his dinner the shoulder of a wren, and for his supper a leg of the same beside his ordinary ounces. The like proportion we mean you shall allow unto our brother of Warwick, saying that we think it meet in respect that his body is more replete than his brother's, that the wren's leg allowed at supper be abated."

He concluded by speaking of the value to the patient provided by the ideal surroundings of Buxton, the pure tonic air and beneficial effects of the thermal waters, an environment admirably supplemented by the up-to-date methods of treatment which now prevailed under the careful and accurate diagnosis of the spa doctors. Sir Squire Sprigge proposed the toast of prosperity to the B.H.R. Association, whose function he said was to collect information about the health resorts to be made available for doctors and their patients. While allowing the natural advantages to be derived in certain circumstances at many well-known continental spas, he said that to seek medical assistance abroad led to a lamentable break in treatment and both this break and the expense could often be avoided if the patient and the doctor knew that treatment similarly appropriate could often be obtained in the British Isles whose varieties of climate and physical geography were so remarkable. The toast was responded to by Dr. W. G. Willoughby, M.O.H., Eastbourne, who called the attention of the company to the diffusion of accurate information in the guide-book of the Association edited by Dr. Fortescue Fox, which now dealt faithfully with the claims made by various centres. The Association, he said, should be duly grateful to the publicity which the press now gave to its efforts, and of the secretary of the Association, Dr. Alfred Cox, he said that he was indefatigable and imperturbable. Dr. Kaye le Fleming, proposing the toast of prosperity to Buxton, said that the town and spa were representing the keenness of the day for the promotion of physical culture. He considered this a very live question, and asked if he was looking too far ahead when he visualised the establishment of health resorts which would cater for a large section of the public—health resorts which would provide something more than treatment for the sick, but baths, gymnasia, and playing grounds for the well. The toast was replied to by the Mayor of Buxton, who pointed out that Buxton possessed many of the necessary amenities, such as beautiful gardens and wonderful air. Their aims until now had been to meet the needs of patients mainly suffering from rheumatic disorders sent to it by the medical profession, but other developments might follow. He said that his council considered the B.H.R. Association as a most valuable friend and he had always recommended that it should obtain financial support. Alderman J. E. Pugh proposed the health of the guests, which was replied to by Prof. F. R. Fraser and Dr. Slocomb, of the Mayo Clinic, Rochester, U.S.A. Prosperity to the new clinic was next proposed by Prof. Arthur Hall, who regarded it as representing concrete evidence of the enormous development of medicine. The treatment of rheumatic patients at the lower end of the social scale had only been possible in big voluntary hospitals and at the other end of the scale sick millionaires got their chance; now at Buxton the sick middle classes had an opportunity. The toast was replied to by Mr. W. F. Wrigley, chairman of the Buxton clinic directors, who said that as usual the promoters of the clinic had been let down by their financial expert whose estimate of the cost had been just 100 per cent. wrong. However, the situation had to be faced and he appealed to the many representatives of music, the drama, art, and journalism present, as well as to his fellow townsmen of Buxton, to give the clinic full support.

Conference of the B.H.R. Association

On Saturday the work commenced with an inspection of the thermal and natural baths under the guidance of local medical men, after which a conference took place in the Hippodrome. Lieut.-Colonel W. Byam, chairman of the medical advisory committee of the B.H.R. Association presided, and began by thanking the Mayor for the hospitality of the borough. He pointed out that the Association was not purely and directly medical, though it existed for health purposes. It held that health centres should be instituted throughout the country, and properly planned. In those that existed reforms should be made, accommodation at hotels should be varied, transport should be made safe and unnecessary noise abated. Besides proper provision of medical care for the patient and suitable amenities, there should be means of entertainment not only for the patients but for the friends who accompany them. He looked forward to the establishment of a diploma for those duly equipped in physiotherapeutics, hydrology, and climatology, and official recognition of a practical sort for approved health resorts. He called upon Sir Landon Ronald, principal of the Guildhall School of Music, to open a discussion upon

THE PLACE OF AMUSEMENT IN THE HEALTH RESORT

"What can be done," asked Sir Landon, "and what should be done to make our own beautiful watering places more attractive?" And he followed by referring to the depressing influence of many post-war restrictions.

"But," he said, "my job in life is music, and I have only referred to these grievances because they play an important part in the problem of what sort of entertainment should be provided at the seaside. A couple of years or so ago I visited several of our most popular resorts during the summer holidays for the purpose of finding out firstly what sort of music was provided for the people; secondly, what sort of bands or orchestras they were asked to listen to; and, thirdly, what sort of performances were given. I must admit to you that I came away a sadder but wiser man. In several cases I found the programmes beneath contempt; I found that the so-called 'orchestra' seldom consisted of more than from six to fifteen instrumentalists; and, lastly, I found that the performances were obviously under-rehearsed and generally ragged and rough. Let me hasten to add that the blame for this was not to be attached either to the conductor (who generally led the band by playing the violin) or to the instrumentalists. The cause of it all was the short-sighted policy of false economy pursued by those who governed the town. Music is still looked upon by many town councillors as one of the most expensive of all objectionable noises."

Sir Landon went on to comment on the absence of any enjoyment in or knowledge of music to be found among civic corporations, making a conspicuous exception in favour of Bournemouth where the corporation had provided a good permanent orchestra under Sir Dan Godfrey, no doubt at much expense, but the residents were convinced that the money was well spent on a magnificent advertisement of the town. His reminiscences of the fine orchestras that existed at different centres in England 30 or 40 years ago were sad, but to the question whether he had any remedy to offer he would reply that there were great London orchestras which had no concert engagements during the summer months, and that these might be engaged say for three weeks at a time to play in large seaside places. Entertainment managers, he said, underrated the public intelligence in thinking that they are as satisfied with half a dozen instrumentalists playing fox-trots as they would be with the London Symphony Orchestra playing beautiful light music—for there was no suggestion that only high-brow compositions should be given; and when the expense was spoken of he would refer to the enormous sums spent by some of these places in promenade and building schemes.

"In suggesting," he concluded, "that one of the great London orchestras should visit these seaside places during July, August, and September, I only do so on the understanding that no such first-class orchestra already exists in the town. I have no wish to disturb the existing local orchestra; they could play for the remaining nine months of the year. But at all events the corporation should see that visitors have the best music that can be obtained for the period when their towns are crowded with visitors and holiday-makers—all spending a great deal of money. And the engaging of a London orchestra would not enter into the scheme of things at all, if the corporation had vision and understanding enough to keep in constant employment a proper small symphony orchestra all the year round; while it must be borne in mind that any local orchestra would deserve a couple of months' holiday annually, and that the residents would enthusiastically welcome a change of orchestra and a change of conductor. My remarks, in which I have constantly alluded to seaside resorts, apply equally to our spas. The story of music in the spas is not a happy one. Some spas which at one time had a good orchestra have fallen from grace. And in none of them is there anything comparable to the fine music that one can hear at several of the continental spas. If our British spas intend seriously to compete in attractiveness with their continental rivals, one or more of them should make a real attempt to show that British spas with British orchestras can equal them in this, as they can do in many other ways."

Mr. St. John Ervine followed with an amusing diatribe on the appreciation manifested by health resort populations, the residents, the visitors, and their friends of good drama. He once brought the Irish players, when at the zenith of their fame, to Buxton, and the kind of audience they got wanted to make him cruel to cripples. He thought that a health resort should not only provide good entertainments but that the inhabitants, especially the municipal authorities, should cultivate cheeriness, and he drew a fantastic picture of councillors in their robes and of lovely aldermen. But the serious message of his address was that a borough in providing amenities for visitors, sick or sound, should include among them the presentation of good drama.

Mr. L. du Garde Peach pleaded the right of young people to be amused when on holiday, and Alderman Harvey, Lord Mayor of Stoke, emphasised this opinion, adding that a large proportion of the population resented the perpetual presentation to them of films that were trashy and entertainments that were vulgar.

Mr. Bonnington, publicity manager, showed that his was a difficult task in dealing with many conflicting interests.

Modern Orthopædics

In the afternoon demonstrations were given of orthopædic methods employed at the Devonshire Hospital, when an interesting series of patients was seen undergoing various forms of manipulative treatment. A plaster bed for spondylitis was made in the presence of the company and the rapidity with which the process could be carried out by expert nurses was remarkable. Methods of taking and recording spinal tracings were shown, the treatment of knees after extension on the Balkan frame, and the different exercises accompanied with splinting to restore comfort, function, and appearance to crippled hands. Dr. L. S. Potter, Dr. L. C. Hill, Dr. C. W. Buckley, Dr. J. A. Hendry, and Dr. J. S. Charlton showed cases under treatment of Paget's disease, von Recklinghausen's disease, early spondylitis, and extreme osteoporosis in rheumatoid arthritis, and all these demonstrations left the firm impression that careful, advanced, and well-directed surgical and medical measures were being taken to counteract conditions and sequelæ in very painful and obstinate diseases.

CRIPPLED CHILDREN

A discussion followed upon the spa treatment of crippling diseases, especially in children. Dr. Buckley presided, and Dr. R. G. Gordon, physician at the Children's Hospital, Bath, opened the discussion. He said :—

"In rheumatic infections of childhood, which come under the general grouping of acute rheumatism, there is seldom if ever any lasting effect in the absence of secondary infection, and the term 'rheumatic' must not be held to be an inevitable indication for hydrotherapy, for in the acute and subacute stages of this infection hydrotherapy in my submission is contra-indicated. Still's disease does not differ from rheumatoid arthritis except that the reactions such as splenic and marked glandular enlargement are what may be regarded as characteristic of the *age* of the patient rather than of the nature of the disease process. In all cases of rheumatoid arthritis at any age in the acute and subacute stages, hydrotherapy of any kind must be used with the greatest care and circumspection, and the orthopædic maintenance of posture and general resistance of the patient are the features which require greatest attention. Acute and subacute fibrositis are now and then met with in children and young adults, and sometimes provoke difficulties in diagnosis with tuberculosis of the spine, especially in those cases of the latter disease of very insidious origin. In such cases of fibrositis hydrotherapy and its adjuvant therapeutic measures have a decided place, provided great care is taken that on any signs of retrogression in the condition of the patient a fresh search is made for tuberculous infection.

"In the orthopædic disorders of children external hydrotherapy has a wide field of usefulness, but I propose to confine myself to the hot pool bath and the consideration of certain physiological effects of this treatment. It is not always recognised that an artificial hyperpyrexia can easily be induced by a hot bath. Acting on the suggestion that hyperpyrexia induced by intravenous administration of T.A.B. was beneficial in chorea, I induced hyperpyrexia in some dozen cases by means of hot baths. There was a rise of temperature to 104° while in the bath at 108°, and the maintenance of a temperature for 2½ hours before it fell to normal. But while benefit was definite it was not maintained any better than with other methods of treatment, and in two cases excitement and violence almost amounting to mania was induced. But except for mild vomiting on two occasions I met with no signs of heat collapse. Immersion in the hot bath results in the hyperventilation of the lungs in an attempt to cool the body. The result of this is to produce a deficiency of carbon dioxide both in the arterial and venous blood and a consequent alkalosis amounting to a 0·09 rise in pH value. There is a transference of water to the blood from the tissues with a relative diminution of hæmoglobin. The purpose of this dilution is to fill the much dilated superficial vessels. Later there may be a concentration of blood due to the loss of water by sweat and urine. With the transference of the water from tissues to the blood there is also a transference of protein and salts, so that the serum becomes richer in these. It would appear that this increase of serum solids is derived from the muscles. Hot baths increase the sugar metabolism and therefore lower the blood-sugar by 9·45 per cent. on the average. The inorganic phosphorus content of the serum is increased by about 4·25 per cent., while the total serum calcium falls to the extent of 3·03 per cent. This latter alteration will result in an increased neuromuscular hyperexcitability as a consequence of hot baths which may in rare cases amount to an epileptiform convulsion or tetany. The type of bath which I prefer for the treatment of orthopædic disorders of childhood is the large pool bath as used at Buxton. We use these baths at Bath more particularly for anterior poliomyelitis in its later stages; neuritis and chronic arthritis; congenital dislocation of the hip; coxa plana, after the head is reasonably firm in the acetabulum and regeneration is well advanced; all types of spastic paralysis. The advantages claimed for the pool bath at temperatures varying between 95–104° are improvement of circulation; relaxation of spasm of the joints so that contractures, whether due to spasticity or even to fibrosis, may be stretched passively or actively; and relief of pain, so that manipulations can be carried out with a minimum of distress. The use of water overcomes the load of gravity at least to the extent of 95 per cent., as proved by Dr. Crowden's experiments."

Dr. Gordon concluded by reminding his hearers that while hydrotherapy is a potent weapon capable of inducing great benefits, it may inflict great harm, as there is scarcely any mechanism of the body which is not affected by it, and crippled children cannot be treated by rule of thumb.

The discussion was continued by Dr. A. H. Douthwaite, assistant physician, Guy's Hospital, and physician in charge of the massage department.

CRIPPLING OF RHEUMATIC ORIGIN

Dr. Douthwaite began by considering the precrippling stages of certain rheumatic conditions in relation to their suitability for physiotherapy. He said :—

"A pre-arthritic stage can be distinguished which particularly in the case of rheumatoid arthritis is characterised by general ill-health, loss of weight, disturbance of sugar metabolism in the direction of lowered tolerance, and the all-important defect of peripheral circulation. This was shown by the cold and clammy extremities, and by the appreciably lower temperature of the hands and feet as indicated by the skin thermometer. These cases were eminently suitable for spa treatment. The acute stage of rheumatism—e.g., sciatica or multiple joint involvement—was best treated at home. In the subacute stage, when the signs of local and general activity of the disease were subsiding, spa treatment was often of benefit in hastening recovery but had to be given with the utmost caution to prevent a relapse. In the stage of convalescence with or without contractures the treatment of patients in an institution equipped with all modern appliances of physiotherapy was to his mind an essential to success."

The speaker then considered the chief aims of spa treatment, which were he said :—

"1. Improvement of peripheral circulation, and most forms of hydro- and electro-therapy did, in fact, achieve this object. He suggested that some of the joint changes in typical rheumatoid arthritis might be directly referable to impaired capillary circulation, and drew attention to the similarity in appearance of the finger-joints in this affection and in a purely vascular disturbance such as Raynaud's disease. He referred also to some excellent results he had attained by treating rheumatoid subjects by means of infection with malaria. Six or seven bouts of fever with the associated flushing of the skin and sweating might restore movement to the stiffened small joints of the rheumatoid arthritic. The treatment should be reserved for the later stages when the active disease was dead or dying. The malaria could be stamped out with two 5-grain doses of Atebrin.

"2. Recovery of muscle bulk. It was clearly useless to restore movement to joints in the absence of muscles capable of their control. This could never be attained by massage, but success could be looked for from static contractions and exercises.

"3. Recovery of movements which has been limited by (*a*) loss of power in muscles; (*b*) loss of habit—a factor greatly underestimated; (*c*) adhesions and muscle contracture; (*d*) muscle spasm which though no doubt of importance in all joint diseases was often overlooked in osteoarthritis of the hip.

"4. Improvement in general condition."

Dr. Douthwaite concluded by saying that no physician with an interest in rheumatic diseases could afford to disregard the otherwise unobtainable facilities for treatment such as are presented by the English spas, and he hoped that the efficiency of their staffs would no longer be hampered by the complete lack of anything worthy of the name of amusement, which had unfortunately driven many patients in the past to foreign resorts.

MANIPULATIVE TREATMENT

Mr. Timbrell Fisher, surgeon to the Seamen's Hospital, Greenwich, and in charge of the special clinic of the Ministry of Pensions Hospital at Orpington, discussed in detail the manipulative treatment of stiffened joints under water, and continued :—

"The value of the various forms of baths in crippling conditions not only of children but of adults is amply clear. With regard to the possibilities of under-water manipulation, the effect of the hot water is to relieve pain and congestion, to relax muscular spasm, and relieve the patient to a great extent of the necessity of supporting the painful limb. The patient thus finds that he is able to carry out movements that were hitherto impossible owing to pain and muscular spasm. These movements must play an important part in the prevention of deformity, since limitation of movement, at first due to muscular spasm, is apt to be followed by the formation of adhesions or scar tissue. This newly formed connective tissue, which is such a potent cause of disability, may occur not only inside the joint but in the joint capsule, in peri-articular structures, and even in connexion with the muscles acting upon the joint. Active and assisted movements performed in the deep pool are particularly useful in those varieties of chronic rheumatic arthritis, whether of the rheumatoid or osteoarthritic types, in which movement is very painful and associated with considerable muscular spasm. Then in addition to the action of such baths in the prevention of deformity, we have been shown that they are of value in the treatment of developed deformity. When the limitation of movement due to muscular spasm is abolished, remaining limitation of movement is due either to scar tissue or may be actually osseous. When due to scar tissue, a forced movement of the joint, when the patient is conscious, is in nearly every case associated with a degree of pain and involuntary muscular spasm, dependent upon various factors, including the skill of the manipulator and the psychological reaction to pain. But even the keenest advocate of the method of under-water manipulation would doubtless admit that, like every method of therapy, it has its limitations. Careful manipulation under anæsthesia must be considered. As the result of many years experience of a series of cases that runs into four figures, it is my considered opinion that manipulation under anæsthesia is an exceedingly valuable procedure in carefully selected cases, and that a great deal of unnecessarily prolonged suffering and financial embarrassment is still caused to sufferers from various crippling disabilities because the great possibilities of manipulation under anæsthesia are not sufficiently realised. Manipulation under anæsthesia is of most benefit where the joints are stiff owing to the presence of traumatic adhesions. Many joints, for instance, develop a painful limitation of some movement after a severe sprain that has been followed by traumatic synovitis. Some cases appear to be a combination of sprain and infection—i.e., the sprain of the internal lateral ligament of the knee or at the site of origin of the common extensors of the wrist and fingers from the external epicondyle of the humerus which, particularly in a middle-aged person, obstinately resists treatment. I believe that in these cases infection has been superadded, and very active treatment, often profitably including manipulation, should be persisted in. Adhesions may occur not only after trauma or trauma with superadded infection, but may be encountered in the more chronic stages of many diseases of joints, as in streptococcal or gonococcal arthritis. A preliminary trial should usually be made of simpler forms of physical medicine such as those which have been so ably demonstrated to us, and it is only when these fail that *manipulation under anæsthesia has to be considered*."

Mr. Timbrell Fisher then outlined the types of case that should benefit by manipulative treatment, of which the most suitable were rheumatoid cases or those of the proliferative kind. In polyarticular cases, he said, no joint should be manipulated, but in many cases of the more chronic type with somewhat dense adhesions a valuable procedure was to correct deformity and increase the range of useful movement by a series of manipulations, between which every effort is made to consolidate the ground gained by the last manipulation and to restore the wasted and weakened musculature. The application of these methods to different types of arthritis of the wrist was described in detail. "Manipulation under an anæsthetic," he held, "was often of value in cases of the osteoarthritic or degenerative type of chronic arthritis associated with deformity or an interference with movement that seriously interferes with function, but it was obvious that the general condition of the patient must be seriously considered before having recourse to manipulation under anæsthesia. In many cases the age and general condition of the patient would rule out any possibility of this method of treatment, which should not be undertaken unless the orthopædic surgeon who performs the manipulation can personally supervise, at any rate, the first part of the after-treatment, often of equal importance to the manipulation."

HOSPITALITY

Throughout the visit of the B.H.R. Association to Buxton the opportunities for hospitality to guests were taken full advantage of by the residents. There were various informal receptions, pleasant drives were planned, and the corporation reserved seats for an excellent performance of "The Arcadians" at the Opera House on Saturday evening.

NEW HOSPITAL FOR LLANDUDNO.—An appeal was made last week for £50,000 to build a new hospital for the town. Six acres of land have been given and the new institution is to have 60 beds. The buildings will be designed to allow of extensions to provide 120 beds.

MEDICINE AND THE LAW

Deaths after HCN Fumigation

THE unfortunate deaths at Aldershot, following the fumigation of vermin-infested cottages with hydrocyanic acid gas, were noted in our columns last week (p. 1021). So valuable is this method of destroying rats and vermin that, in spite of the recent reminder of its dangers, prohibition of its use is inadvisable. It is not an ordinary disinfectant; it has no effect upon the plague bacillus, but it kills the rats and fleas which carry the bacillus. Apart from its aid to public health in destroying the louse, the bug, the flea, and the mosquito, its economic services are well established. Employed in 1886 as an insecticide to destroy the scale pests of citrus trees in the United States, its utility for this purpose spread from California and Florida to Australia, Japan, and South Africa. In 1898 it was applied to destroy vermin in the Cape Government Railway's sleeping carriages, in 1901 to free prison buildings at the Cape from the bed-bug. Experiments in 1909 having proved its lethal effect upon rats and fleas in India, it soon afterwards became an authorised fumigant under the Quarantine Regulations of the United States. Having cleared a German flour mill of weevils in 1917, it successfully attacked plague-infected rats in the granaries of Venice in 1919. It is now perhaps best known as a process for the deratisation of ships, but it has lately been employed to free houses from vermin on the London County Council building estates. Whether it works for public health or for commerce, its action is swift and efficient. In contrast with sulphur it involves neither danger of fire nor damage to paint, metal work, fittings, or cargoes. But the gas is fatal to human beings and its smell gives scant warning. It is too useful to prohibit, yet too risky to leave unregulated; and fuller consideration of the evidence at the Aldershot inquest shows that, in spite of ample warnings in text-books, the present law is quite inadequate to control its use. No Act of Parliament requires that the commercial use of cyanide by private firms as a fumigant shall be subject to any system of licensing. The Home Office has made no rules for cyanide fumigation as a dangerous trade. The Ministry of Health has apparently no power to prescribe by regulations the method of such fumigation or the precautions to be taken before men, women, and children are allowed to return to the premises which have been thus fumigated.

THE ALDERSHOT INQUIRY

Our brief account last week of the fatal incidents at Aldershot may be expanded to show the situation with which the law should deal. The health committee of the borough council sees a free demonstration by a private company of the undoubted potency of hydrogen cyanide in fumigating verminous dwellings. It ascertains that the process has been successfully applied by other local authorities. The committee is rightly satisfied of the merits of the method and recommends its adoption at a cost of £5 per house or £2 10s. where four or more houses are treated. The committee advises the council that it will be necessary either for alternative accommodation to be found for the tenants for one night, or for the bedding to be removed for steam disinfection and returned the same day. The council adopts the plan and the tenants vacate their cottages from 10 A.M. on April 11th till 10 A.M. next The fumigator, who has plenty of experience o work, puts on a gas-mask, enters the premises, distributes (on the floor or between mattresse otherwise) paper discs which have absorbed the he also sprays the cyanide in liquid form. He comes out, seals up the front doors and posts not At night he comes back, opens the doors, goe and collects all his discs, throws open all wind cupboards, and drawers. He uses some me of testing the atmosphere by means of blott paper dipped in a certain solution; he also r on his sense of smell. Satisfied that all is he takes the keys of the cottages to the office of sanitary inspector in an envelope inscribed "Ev thing O.K." The inspector receives the keys morning and allows the tenants to return to t homes as arranged. The fumigator has followed previously harmless and successful routine, and sanitary inspector believes him to be expert in own technique and has his message of assur of safety. No warning is given to the tena Witnesses from two of the cottages told the cor they detected no particularly suspicious od a witness from a third cottage said he notice nasty smell. Before breakfast-time next day children are dead and other occupants of the prem have narrowly escaped.

The warnings in the text-books against the r of hydrogen cyanide are in rather general te A detailed statement is to be found in a Mini of Health report[1] published in 1923 and wri by Dr. P. G. Stock and Dr. G. W. Mor Williams, who are in possession of special knowle and experience respectively of port sani administration and of military measures aga gas attacks. The report classifies accidents occurring during the generation of the gas, du actual fumigation, during subsequent ventilat and afterwards when the premises have b pronounced clear. In one case in 1915, descri by Dr. Benjamin Cohen,[2] a man who had o fumigated bug-infected rooms by pouring sulph acid on potassium cyanide and then rushing of the room and pulling the door behind h unfortunately reopened the door because he he the cry of a cat. He was found unconscious in fr of the door. In other cases employees have been moved quickly enough out of a ship when gas was being generated, or else unauthorised pers have entered premises under fumigation. In 1 we recorded an incident in Chicago[3] where a ba ment restaurant was being fumigated to dest cockroaches; an opening for a water-pipe was ov looked and the leakage of gas killed six people i second-floor room upstairs. The Aldershot inqu illustrates the risks of ignorance. Other examples h been given by H. Fühner[4] of Königsberg. He descri an occasion when 100 soldiers, whose clothes l been deloused by hydrogen cyanide, suffered fr poisoning within an hour of putting them on ag There were no deaths, but ten men lost consciousn The extent to which particular materials retain gas in their air spaces is a fit subject for furt research.

SUGGESTED PRECAUTIONS

A more recent report issued by the Ministry

[2] South African Med. Record, 1925, xiv., 35.

[3] THE LANCET, 1923, i., 762.

[4] Deut. Med. Woch., 1919, xlv., 847.

Health, on the Bed-bug,[5] suggests various precautions. Fumigation by hydrogen cyanide, it says, should be undertaken only by persons with full knowledge of the nature of the gas. A house must be kept empty till it is certified free from gas; if it is not completely detached, the houses on each side must also be kept vacant for about eight hours and be kept under observation by men trained to detect possible leakage of the fumigant. Dissipation is slow in cold weather and repeated tests may be necessary; it may even be proper to close and warm the rooms before testing afresh. Bedding, blankets, pillows, and stuffed furniture should be beaten in the open air before re-use. The Ministry's earlier report of 1923, already referred to, drew attention to the need of care in handling and storing solid cyanide, in washing receptacles wherein it has been contained, and in the avoidance of splashing. The substance is often sent out in square tins with circular openings and thus small amounts may remain as a source of danger. Residuals after fumigation must be regarded as poisonous. As much care is needed during subsequent ventilation as during actual fumigation. In work on ships conspicuous notices should be posted and a special flag is suggested. The vessel must be completely searched, a single gangway should be used, and a careful tally kept of persons who go aboard and come ashore. The fumigating gang should work from leeward to windward and from the top deck downwards; possible pockets of gas should be looked for and doubtless naval architects are bearing this point in mind in modern ship construction. Fumigators should work in pairs and the use of electric torches and of life-lines should not be forgotten. As the evidence at the Aldershot inquest showed, and as the text-books state, the sense of smell should not be relied upon. It is said that one of the quickest ways of detecting the gas in low dilutions is by the peculiar taste apparent when smoking. Self-contained oxygen breathing apparatus, if in perfect order and worn by a trained man, gives protection against the highest concentrations of gas likely to be encountered, but is cumbersome and heavy. The army type of "small box respirator," filled with a mixture of alkaline permanganate granules and activated charcoal, costs little, is light to carry, and requires no elaborate training; but the granules gradually become damp, and, after an aggregate use for about 24 hours, a new box must be fitted.

A person overcome by the fumes must be removed to the fresh air at once. In this connexion the Ministry's report deprecated attempts at rescue unless the rescuer is protected by a mask or can be hauled back to safety by a life-line. Neglect of precautions by the rescuer has, it seems, often added to the total of fatalities without effecting a rescue. Artificial respiration should be begun immediately. Prof. Barcroft has suggested the addition of carbon dioxide to stimulate the respiratory centre. A special inhaler, fitted with the Gibbs valve, has been used in New York for administrating oxygen containing 5 per cent. of CO_2; oxygen administered alone is of doubtful value. The authors of the Ministry's report of 1923 were told at the Quarantine Station at New York that the only remedy there found of any avail was artificial respiration with possibly hypodermic injections of camphor and the use of a galvanic battery. Fühner advises subcutaneous injection of 5 per cent. sodium hyposulphite up to 100 c.cm. or more; strychnine and caffeine, he thinks, merely increase the "cramps" without relief to the breathing.

The Aldershot case was one which should somehow have been prevented. The Ministry's report on the bed-bug expressly states that at present there is no statutory power to make regulations for the control of fumigation with cyanide or other poisonous gases. Here is something useful for Parliament to do.

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

GLASGOW APPOINTMENTS COMMITTEE

THE value of the Glasgow University Appointments Committee was emphasised at last week's graduation ceremony by Sir Robert Rait, the vice-Chancellor and principal. In the year 1934–1935 only 27 of the 638, graduates failed to communicate with the committee and only 48 were known to be unemployed. A feature of the past year was the number of arts students who found openings in industry and commerce. The principal appealed to young graduates to keep in touch with the committee; this is particularly important in the case of medical graduates, since the work of the committee is of special value to the young doctor after he has had some post-graduate hospital experience. Many inquiries for assistants and possible partners reach the committee, and it is sometimes difficult to get suitably qualified men in time.

It is often said of universities that interest in the student ceases as soon as he graduates. Every effort, therefore, to overcome this reproach will be welcome. It is a deplorable fact that many students graduate in medicine with little knowledge of what their profession has to offer, and with even less knowledge of how to plan their career, and it is satisfactory to find that university authorities are alive to the importance of instructing their graduands how best to make use of the knowledge they have acquired.

An organisation such as the Edinburgh Graduates Association is of great value in keeping graduates in touch with their university. The Association sends to its members the well-produced *University Journal* which is published twice yearly. It not only informs its members of university happenings, but encourages the development of university clubs all over the world. It has assisted student activities, especially in the direction of encouraging athletics, and has been able to help students who, through no fault of their own, have found themselves in pecuniary difficulties. It has recently been suggested that a similar association should be formed in connexion with the University of Aberdeen.

EDINBURGH CHARITIES WEEK

Last week was charities week in Edinburgh. The energy, enthusiasm, and ingenuity of the students has been well maintained, and as the weather has been favourable, a large sum will have been collected for the local hospitals. Unfortunately the week has been marred by a fatal accident to a student performing at the students' carnival in the Waverley Market. His "side-show" consisted in diving through a hoop into a canvas bath. The latter contained only a few feet of water, and a slight error of judgment caused him to touch the hoop, so that instead of making the necessary flat dive, he fell more vertically and fractured his skull against the bottom of the bath. Further supervision of the carnival is surely necessary when such obviously dangerous stunts are practised.

THE FIRST CHEMICAL SOCIETY

The Chemical Society of Philadelphia, founded in 1792, has been considered the first society of its kind in the world. Prof. James Kendall of Edinburgh University, however, has established the fact that a chemical society existed in Edinburgh in the year 1785. He suggests that the Philadelphia Society was the daughter of the one in Edinburgh, since the medical school of Philadelphia was instituted in 1765 under strong Edinburgh auspices.

PARLIAMENTARY INTELLIGENCE

HOUSE OF COMMONS

Reassembly after Easter

The House of Commons reassembled after the Easter adjournment on Monday, April 29th.

MONDAY, APRIL 29TH

Cleansing of Shell-fish

Mr. Oswald Lewis asked the Minister of Agriculture if, in the course of his inquiry as to the desirability of making an order for the compulsory cleansing of shell-fish before they were marketed, he would consider the propriety of exempting from the operation of such an order a fishery such as the Colchester oyster fishery where, owing to the situation of the beds and the set of the tides, pollution of the shell-fish was not possible.—Mr. Elliot replied: My right hon. friend, the Minister of Health, by whom regulations for the control of the sale of shell-fish for human consumption are made, will no doubt be guided by the evidence of pollution or of its absence. The inquiries which we are conducting are directed to this point. If my hon. friend will give me any evidence as to beds in which pollution is impossible, I shall be glad to examine it.

Aldershot Fumigation Deaths

Mr. Thorne asked the Minister of Health if he had received a copy of the jury's recommendation in connexion with the death of two children by cyanide poisoning after their home had been fumigated at Aldershot; if he was aware that the work was done by contract; if he would make it clear to all local authorities that such work should be carried out directly by the local authority; and whether the parents of the two deceased children had received any compensation from the Aldershot local authority.—Sir Hilton Young replied: The answer to the first two parts of the question is in the affirmative. I do not think that the suggestion made in the third part of the question, that the work of fumigation should be carried out directly by the local authority, would make for greater safety or efficiency. As regards the last part of the question, I understand that the question of compensation for the parents of the two deceased children is under consideration, and that allowances have been paid by the Aldershot Town Council to the tenants in respect of food and lodging for the period during which they were dispossessed of their houses.

Supply of Milk to School-children

Mr. McEntee asked the Parliamentary Secretary to the Board of Education the number of children being supplied with milk in all schools in the county of London, and the number being supplied free.—Mr. Ramsbotham replied: Complete returns are not yet available, but it appears from the information so far received that at the end of March about 365,000 children and young persons in grant-earning schools in the county of London were being supplied with milk, of whom about 26,700 were receiving milk free of charge.

Telephones in Rural Areas

Replying to Major Attlee, Sir Kingsley Wood, Postmaster-General, said: I think it will be recognised that the reductions which were introduced towards the end of last year were far-reaching in their scope, and they have largely contributed to an unprecedented telephone development in this country. There is, however, I believe still considerable scope for telephone expansion in our rural areas, which would also do much to assist our farmers and also others who live in remote areas of the country. We are now about to take steps which will aim at making the telephone available in rural and remote parts of the country as readily as it is in the cities and towns to-day. This must necessarily take time fully to accomplish, but as the first step I now propose to ensure, so far as practicable, that by the end of 1936 no village on the mainland of Great Britain and Northern Ireland, which has a post office, will be without a public telephone. This will mean an addition of over 1000 additional public telephone call offices in these parts of the country which have hitherto been unable to possess that easy and rapid communication which our telephone system affords to-day.

TUESDAY, APRIL 30TH

Coloured Men and Alleged "Rare Disease"

Captain A. Evans asked the Minister of Health if he had any information regarding the outbreak of a rare and complicated disease reported to have affected a number of coloured men in the Bute area of Cardiff, some of whom were engaged in the filming of "Sanders of the River," resulting in at least half a dozen deaths.—Mr. Shakespeare, Parliamentary Secretary to the Ministry of Health, replied: The answer is in the negative. Inquiries which have been made have failed to confirm the occurrence of any such outbreak as that referred to in the question. My right hon. friend is informed that only one coloured man has recently died in this area, and the cause of death was found after a post-mortem examination to be arterio-sclerosis and aortitis.

Constitution of Durham University

Mr. Martin asked the Parliamentary Secretary to the Board of Education whether he could announce the probable date of the appointment of commissioners to form a new constitution for Durham University.—Mr. Ramsbotham replied: The Government have decided to introduce early legislation to set up commissioners to prepare statutes in general accordance with the commission's recommendations.—Replying to a further question Mr. Ramsbotham said that it was hoped to introduce the Bill in the House of Lords before Whitsuntide.

Modern Churchmen's Union.—A week-end conference is being held by this union at Old Jordans Hostel, Beaconsfield, Bucks, from May 18th to 20th, the subject being psychology and life. The speakers will include the Rev. L. F. Browne, M.D., physician to the Institute of Medical Psychology (psychology and religious experience), and Dr. Burnett Rae (psychology and health). Particulars may be had from the organising secretary at the Church House, Westminster, London, S.W. 1.

Mock Trials.—A series of mock trials will be held at the London School of Economics, Aldwych, on Tuesdays from May 14th to June 25th at 5.30 P.M., in aid of King Edward's Hospital Fund for London. On May 14th Mr. Philip Guedella will prosecute the cinema for misappropriating history, while on May 21st the ballet will be arraigned on the charge of not planting their feet firmly on the ground. On May 28th Mr. St. John Ervine will accuse airmen of making the world too small. On June 4th the ancient Greeks must answer the charge of not knowing that they are dead, and on June 18th modern authors that of taking themselves too seriously. At the last trial on June 25th Mr. Punch has entrusted his defence for being unduly polite to Mr. E. V. Knox, his editor. The secretary of the fund may be addressed at 10, Old Jewry, London, E.C. 2.

PANEL AND CONTRACT PRACTICE

The Economy Deductions

ALONG with certain other classes of the community insurance doctors and chemists regain their standard remuneration on July 1st when, under Mr. Chamberlain's fourth Budget, the remaining half of the salaries cuts of 1931 is restored. The present is, perhaps, a convenient opportunity to indicate the effect of these cuts on the doctors. It will be remembered that the deduction took effect as from Oct. 1st, 1931, and was at the rate of 10 per cent. until July 1st, 1934, when it was reduced to 5 per cent. The actual amounts of the deductions suffered by practitioners are (1931) £165,826, (1932) £672,813, (1933) £675,318, (1934) £500,743, and upon the provisional determination of the fund for 1935 it is estimated that the 5 per cent. cut for the first six months will amount to just over £159,000. The total deductions therefore from insurance doctors, apart of course from the increased taxation to which they in common with the rest of the community have been subjected, will have amounted in round figures to £2,174,000 for England alone.

Medical Certification

Insurance doctors are sometimes asked for certificates which they are not properly called upon to issue. A case in point is that in which an insured person has been examined by a regional medical officer and reported not incapable of work. Sometimes the agent of the approved society tells the patient to obtain a final certificate from the insurance doctor, and says he cannot pay the balance of sickness benefit until the certificate has been produced. It may be that the insurance doctor does not agree with the R.M.O.'s report that the patient is not incapable of work, and in such cases it is clearly his duty, if asked by the patient, to continue to issue intermediate certificates unless and until he is satisfied that the patient is no longer incapacitated. But if the insurance doctor does not disagree with the R.M.O., and provided that the date of the examination falls within the period covered by an intermediate certificate already issued, it is not necessary for a further certificate to be issued. The Ministry of Health in August, 1934, intimated that approved societies have now been advised that where benefit is discontinued following upon a R.M.O.'s report that in his opinion the insured person is not incapable of work, they might reasonably regard the production of a declaring-off certificate as unnecessary, and that they should be prepared to pay benefit up to the date of the examination. If, in the circumstances indicated above, the payment of sickness benefit is refused, the insured person should be advised to consult the district inspector of the Ministry of Health.

Another point affecting certification which still gives rise to misunderstanding is the period covered by an intermediate certificate. No. 5 of the Medical Certification Rules provides that, if incapacity continues beyond eight days from the date of the first certificate, further intermediate certificates shall be given by the practitioner, if so desired by the insured person, week by week, during the continuance of incapacity, and for the purpose of the certification rules "week" means the period from midnight on one Sunday to midnight on the following Sunday. If, therefore, an intermediate certificate has been issued on a Monday in any week the next certificate may be issued at any time up to and including the following Sunday week.

A case recently arose in which an insured person having been in receipt of certificates of incapacity since Dec. 31st, 1934, was issued an intermediate certificate on Tuesday, Jan. 29th, 1935. On the following Saturday week, Feb. 9th, the insurance doctor saw the patient and issued a final certificate. An approved society official demanded in addition an intermediate certificate dated Feb. 5th, that is, one week after Jan. 29th.

The definition of "week" in the rules was deliberately framed so as to avoid placing on insurance doctors any obligation to issue certificates on the same day in each week, and while it may be convenient for certificates to be issued as far as possible at weekly intervals, the primary consideration in the mind of the doctor must be the condition of the patient and not merely the question of the issue of a certificate. In the case referred to above the doctor acted perfectly correctly in issuing a final certificate on Saturday, Feb. 9th, and it is a little surprising that an official should have been unable to construe the rules.

PUBLIC HEALTH

Grievances in Huddersfield

WAVES of scarlet fever and diphtheria have swept over Huddersfield in recent years. As is quite usual, their high prevalence has coincided closely in time, taxing the accommodation of Mill Hill Isolation Hospital, so that some overcrowding has occurred. The hospital contains 128 beds, not inadequate in proportion for a town with a population of 114,000 persons, although a small number of patients are admitted from other districts. To relieve pressure the small-pox hospital and wards in a poor-law hospital have been used for infectious cases, but it has been impossible to avoid some overcrowding both of the wards and of the nurses' home. Apparently a good deal of cross-infection has occurred, and this and other supposed defects of administration have been the subject of acrimonious criticism in the correspondence columns of the local press. As Dr. J. M. Gibson, the medical officer of health, explained in an interview, the most careful scrutiny of patients on admission cannot possibly detect a person incubating a second infection, and when two diseases are prevalent, and almost equally so, a high proportion of doubly infected admissions is to be expected. As so often happens during a mild outburst of public hysteria, some real mishappenings have been grossly exaggerated and unfounded suspicions of mismanagement have been aroused, which Dr. Gibson's statement should dispel. The health committee are well forward with plans for an extension of two new blocks at the hospital, presumably with nurses' accommodation in proportion, and these will consist mainly of small cubicles appropriate for dealing with just such administrative problems as have been experienced recently.

Here is another illustration of the intricacies of fever hospital administration. A hospital big enough for normal times may be half empty for long periods and yet be totally inadequate during the periodic waves of the zymotics. In Huddersfield spare beds in quiet times have been wisely used for advanced cases of tuberculosis, but their exclusion in recent years has complicated the administration of a sanatorium not meant for late cases. In other towns measles and whooping-cough are admitted to vacant wards, but these diseases do not always conveniently occur when scarlet fever and diphtheria are in the trough of their seasonal wave. Rigid selection of scarlet fever, a mild disease in its present form, may obviate overcrowding, and this is a policy which has been safely followed in some areas. It is apparently not favoured in Huddersfield, for in 1933, when pressure on the hospital beds was already acute, 806 cases were admitted, being 96·5 per cent. of all cases notified. It cannot be that the housing conditions of Huddersfield are worse than those of Glasgow, where home treatment on a considerable scale has proved practicable. Again, the possible future effect of immunisation, especially against diphtheria, must influence the deliberations of local authorities as to hospital extension. This prophylactic measure has been pressed forward in Huddersfield, and although the immunised population had not reached dimensions sufficient to affect the incidence by the end of 1933, over 4000 children had been dealt with, among whom only two had contracted diphtheria, and that before the necessary time to develop the maximum immunity had elapsed. While additional beds at isolation hospitals are certain to prove useful for the treatment of measles, whooping-cough, pneumonia, acute rheumatism, and other acute diseases, and the demand for institutional treatment is certain to increase, it may be well to anticipate a great fall in the incidence of diphtheria and in the need to admit scarlet fever cases, as the people become more enlightened in their views, and as housing conditions improve.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 20TH, 1935

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 0; scarlet fever, 2007; diphtheria, 1072; enteric fever, 25; acute pneumonia (primary or influenzal), 1361; puerperal fever, 53; puerperal pyrexia, 79; cerebro-spinal fever, 26; acute poliomyelitis, 2; acute polio-encephalitis, 2; encephalitis lethargica, 3; dysentery, 18; ophthalmia neonatorum, 77. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 27th was 3546, which included: Scarlet fever, 1057; diphtheria, 1517; measles, 27; whooping-cough, 399; puerperal fever, 18 mothers (plus 3 babies); encephalitis lethargica, 269; poliomyelitis, 2. At St. Margaret's Hospital there were 15 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In 121 great towns, including London. there was no death from small-pox or enteric fever, 29(1) from measles, 10 (1) from scarlet fever, 29 (1) from whooping-cough, 32 (3) from diphtheria, 44 (14) from diarrhœa and enteritis under two years, and 167 (23) from influenza. The figures in parentheses are those for London itself.

The number of influenzal deaths is on the wane. This week deaths were reported from 62 great towns, Manchester reporting 21, Leeds, 9, Liverpool and Birmingham each 6, Portsmouth 5, Middlesbrough, Salford, and Sunderland each 4. (During the same week Glasgow reported 8 deaths, Edinburgh 1.) Five fatal cases of measles occurred at Wigan, 3 at Chester. Liverpool reported 4 deaths from whooping-cough, Manchester and Middlesbrough each 3. West Ham and Liverpool each had 3 fatal cases of diphtheria, no other great town more than 2.

The number of stillbirths notified during the week was 283 (corresponding to a rate of 47 per 1000 total births), including 42 in London.

CORRESPONDENCE

SALT LOSS AS A CAUSE OF ILL-HEALTH

To the Editor of THE LANCET

SIR,—I was much interested in Colonel McEwen's letter in your last issue; it fills in a curious gap in our knowledge. A rather severer form of the condition he calls attention to has been described by various workers in tropical climates as affecting Europeans there, under the label "functional hypoadrenalism." Some of the cases were helped by cortical extract. Now we know that Addison's disease is accompanied by a great excretion of sodium chloride, and can be symptomatically alleviated by giving this salt. We can understand why these tropical cases simulate some of the symptoms of Addison's disease. No doubt cortical extract may diminish the loss of salt in these patients, but giving salt as Colonel McEwen suggests is both more rational and much more economical. Moreover, his observation explains the achlorhydria which has been found in the type of case to which I am alluding. Salt deprivation is known to diminish the formation of hydrochloric acid. Incidentally, should not all this diminish the zest still displayed in some quarters for prescribing a salt-free diet? The grounds on which Widal recommended this in the treatment of œdema have been abundantly disproved, and Colonel McEwen's observations suggest that this method is inadvisable in asthenic states generally.

I am, Sir, yours faithfully,

W. LANGDON-BROWN.

Cambridge, April 29th.

THE PROBLEM OF DIPHTHERIA

To the Editor of THE LANCET

SIR,—There is so much common ground between myself and Surgeon-Captain Dudley that there is little room for controversy. Nevertheless, his letter in your issue of April 13th (p. 902) leaves certain issues open. The main points of my letter of March 23rd were twofold. First as to any certainty or even probability of an increase in the numbers of carriers following inoculation against diphtheria. There has been a tendency to regard the experiences of the Greenwich Hospital School as if they constituted a crucial experiment. I think that Surgeon-Captain Dudley and his co-investigators will agree that they cannot be so interpreted. The comparison of the incidence of carriers in the school before and after inoculation (in 1928) is, in my opinion, vitiated by three points of difference:—

(1) The certain presence of a *gravis* infection in the third term of 1932 when 1296 boys were swabbed in a 10·9 per cent. of swabs were positive; it was inferred that *gravis* types were present in the school before inoculation but this must be regarded as uncertain. The report itself states (p. 31) that the outbreak in the third term of 1932 "cointided with the introduction of the Leeds serological type of '*gravis*' bacilli into the school." Incidentally the large proportion that the large number of swabs taken in this third term bears to the total "after inoculation" swabs—1276 out of 6354—overweights the total. The comparisons would only be just if the swabs had been taken at a steady rate throughout the whole of the period of observation—probably an impracticable ideal.

(2) The much higher proportion of virulent diphtheria

PANEL AND CONTRACT PRACTICE

The Economy Deductions

ALONG with certain other classes of the community insurance doctors and chemists regain their standard remuneration on July 1st when, under Mr. Chamberlain's fourth Budget, the remaining half of the salaries cuts of 1931 is restored. The present is, perhaps, a convenient opportunity to indicate the effect of these cuts on the doctors. It will be remembered that the deduction took effect as from Oct. 1st, 1931, and was at the rate of 10 per cent. until July 1st, 1934, when it was reduced to 5 per cent. The actual amounts of the deductions suffered by practitioners are (1931) £165,826, (1932) £672,813, (1933) £675,318, (1934) £500,743, and upon the provisional determination of the fund for 1935 it is estimated that the 5 per cent. cut for the first six months will amount to just over £159,000. The total deductions therefore from insurance doctors, apart of course from the increased taxation to which they in common with the rest of the community have been subjected, will have amounted in round figures to £2,174,000 for England alone.

Medical Certification

Insurance doctors are sometimes asked for certificates which they are not properly called upon to issue. A case in point is that in which an insured person has been examined by a regional medical officer and reported not incapable of work. Sometimes the agent of the approved society tells the patient to obtain a final certificate from the insurance doctor, and says he cannot pay the balance of sickness benefit until the certificate has been produced. It may be that the insurance doctor does not agree with the R.M.O.'s report that the patient is not incapable of work, and in such cases it is clearly his duty, if asked by the patient, to continue to issue intermediate certificates unless and until he is satisfied that the patient is no longer incapacitated. But if the insurance doctor does not disagree with the R.M.O., and provided that the date of the examination falls within the period covered by an intermediate certificate already issued, it is not necessary for a further certificate to be issued. The Ministry of Health in August, 1934, intimated that approved societies have now been advised that where benefit is discontinued following upon a R.M.O.'s report that in his opinion the insured person is not incapable of work, they might reasonably regard the production of a declaring-off certificate as unnecessary, and that they should be prepared to pay benefit up to the date of the examination. If, in the circumstances indicated above, the payment of sickness benefit is refused, the insured person should be advised to consult the district inspector of the Ministry of Health.

Another point affecting certification which still gives rise to misunderstanding is the period covered by an intermediate certificate. No. 5 of the Medical Certification Rules provides that, if incapacity continues beyond eight days from the date of the first certificate, further intermediate certificates shall be given by the practitioner, if so desired by the insured person, week by week, during the continuance of incapacity, and for the purpose of the certification rules "week" means the period from midnight on one Sunday to midnight on the following Sunday. If, therefore, an intermediate certificate has been issued on a Monday in any week the next certificate may be issued at any time up to and including the following Sunday week.

A case recently arose in which an insured person having been in receipt of certificates of incapacity since Dec. 31st, 1934, was issued an intermediate certificate on Tuesday, Jan. 29th, 1935. On the following Saturday week, Feb. 9th, the insurance doctor saw the patient and issued a final certificate. An approved society official demanded in addition an intermediate certificate dated Feb. 5th, that is, one week after Jan. 29th.

The definition of "week" in the rules was deliberately framed so as to avoid placing on insurance doctors any obligation to issue certificates on the same day in each week, and while it may be convenient for certificates to be issued as far as possible at weekly intervals, the primary consideration in the mind of the doctor must be the condition of the patient and not merely the question of the issue of a certificate. In the case referred to above the doctor acted perfectly correctly in issuing a final certificate on Saturday, Feb. 9th, and it is a little surprising that an official should have been unable to construe the rules.

PUBLIC HEALTH

Grievances in Huddersfield

WAVES of scarlet fever and diphtheria have swept over Huddersfield in recent years. As is quite usual, their high prevalence has coincided closely in time, taxing the accommodation of Mill Hill Isolation Hospital, so that some overcrowding has occurred. The hospital contains 128 beds, not inadequate in proportion for a town with a population of 114,000 persons, although a small number of patients are admitted from other districts. To relieve pressure the small-pox hospital and wards in a poor-law hospital have been used for infectious cases, but it has been impossible to avoid some overcrowding both of the wards and of the nurses' home. Apparently a good deal of cross-infection has occurred, and this and other supposed defects of administration have been the subject of acrimonious criticism in the correspondence columns of the local press. As Dr. J. M. Gibson, the medical officer of health, explained in an interview, the most careful scrutiny of patients on admission cannot possibly detect a person incubating a second infection, and when two diseases are prevalent, and almost equally so, a high proportion of doubly infected admissions is to be expected. As so often happens during a mild outburst of public hysteria, some real mishappenings have been grossly exaggerated and unfounded suspicions of mismanagement have been aroused, which Dr. Gibson's statement should dispel. The health committee are well forward with plans for an extension of two new blocks at the hospital, presumably with nurses' accommodation in proportion, and these will consist mainly of small cubicles appropriate for dealing with just such administrative problems as have been experienced recently.

Here is another illustration of the intricacies of fever hospital administration. A hospital big enough for normal times may be half empty for long periods and yet be totally inadequate during the periodic waves of the zymotics. In Huddersfield spare beds in quiet times have been wisely used for advanced cases of tuberculosis, but their exclusion in recent years

1929, ii., 363) in the seborrhœic state and for those who are subject to repeated colds or to chronic nasopharyngeal catarrh. Until I had read Földes's work I did not realise that the same dietetic principles might be indicated in allergic conditions; in fact, I had wrongly advised to the contrary.

The rationale of the antiretentional dietary is based on the fact that excess of carbohydrates and of fats causes retention of water and minerals, whereas proteins and nucleoproteids in particular have the opposite effect. Such a dietary is similar to that advocated by Czerny in the exudative diathesis, and by Minot and Murphy in pernicious anæmia. Briefly, it contains a relatively high proportion of proteins and foods containing nucleoproteins, whereas the intake of carbohydrates and fats is restricted, as also is that of fluid and salt. No ill-effects result from a high protein consumption, *provided that there is adequate restriction of carbohydrates and fats*. I am convinced that the modern fashion of advising the administration of large quantities of carbohydrates to children is wrong: it predisposes to the "watery" condition of the mucous membranes which renders the subject susceptible to the colds and chronic nasopharyngeal infections that Dr. Paterson considers to be the commonest provoking factors in cyclical vomiting.

As an example of the remarkable effects of an antiretentional diet the following case may be cited.

A boy of 15 was referred to my out-patient department by one of my colleagues last summer for a recurrent impetiginous anterior rhinitis, which nearly always resulted from his frequent colds. He was subject to repeated asthmatic attacks, and had so-called functional albuminuria. His mother stated that the boy consumed large quantities of sweets, jam, pudding, cake, and bread: his intake of fat was probably also excessive. I advised a strict antiretentional diet, which the mother promised to enforce. A fortnight later I saw the boy again. His rhinitis and chronic catarrh had cleared up, the albuminuria had disappeared, and his mother was astonished at the improvement in his general health. Since that time he has had no colds and has been entirely free from asthma, except at Christmas when his mother allowed him to relax his diet. He then promptly "caught a cold" and had several asthmatic attacks. Since resuming the diet he has been perfectly well.

While agreeing with Dr. Paterson that acute infections or chronic foci of infection predispose to the attacks of cyclical vomiting and allied symptoms in those who are constitutionally subject to them, my contention is that a predisposition to catarrhal infection, with the inevitable lymphoid hyperplasia that results from it, is dependent on a faulty diet which tends to cause fluid retention.

I am, Sir, yours faithfully,

H. W. BARBER.

Devonshire-place, W., April 23rd.

To the Editor of THE LANCET

SIR,—Dr. Donald Paterson has obviously performed a useful action in warning against the dangers of accepting evidence of ketosis as a complete diagnosis. The clinical diagnosis "acidosis attack" can only be reached fairly by a process of exclusion of all infective cause. But when this has been done—and after vomiting and dehydration I do not look upon pyrexia only as sufficient evidence of infection—I am convinced that there remains a large group which Dr. Paterson, perhaps in his anxiety to avoid mis-diagnosis, of the admittedly much larger infective group, glossed over very scantly. I refer to the children who produce an attack repeatedly under the influence of excitement—e.g., a visit to the Zoo, a theatre, or a party, or by over-exertion, or by riding in some vehicle. They may of course themselves not infrequently be really acidotic with an infection, but the common attacks of the group of children of which I am speaking will again and again baffle the attempts to find an infective origin.

My point is this: Just as I entirely agree that infective acidosis is very common and demands no treatment between infections, I do plead that Dr. Paterson does not swing us to the other extreme and discourage treatment by higher carbohydrates and moderate restriction of fats of the child who has these frequent distressing and annoying periods of vomiting. Dr. Paterson implies that the result of such treatment has been severe dental decay: the extra carbohydrate need not be given as cereals. He also speaks as though malnutrition had resulted, but could he guarantee to fatten many of the children of the type in question? Surely he is being too hard on the dietetic modification which really need only consist in the addition of a tablespoonful of glucose powder four times a day apart from meals, and the subtraction from the normal diet of chocolate, meat fats, and cream. It is interesting that the children of the non-infective "acidotic attack" type are very commonly constant fat refusers, as has been pointed out by Dr. H. C. Cameron, and seem much fitter if their natural dislike is allowed.

Admittedly the attacks are rarely severe enough to justify admission to hospital, thereby somewhat modifying the statistical value implied in Dr. Paterson's statement of the admission rate at Great Ormond-street; but the relief and satisfaction of the parents, let alone of the children, at the control of the attack is justification enough for continuous treatment in the group to which I have confined this letter.

Matters of value in medicine frequently excite the return of the swing of the pendulum by their too enthusiastic application to an unjustifiably wide range of conditions. It is to be hoped that the usefulness of the dietetic modifications associated particularly with Dr. H. C. Cameron's name be not lost sight of as a result of the mistakes of his followers.—I am, Sir, yours faithfully,

F. HARWOOD STEVENSON.

Edgware, Middlesex, April 29th.

THE KNEE-JERK IN PNEUMONIA

To the Editor of THE LANCET

SIR,—I trust I have not misunderstood Dr. Stoddart's reference to the state of the knee-jerk in lobar pneumonia in his letter in which he so eloquently extols the genius of Hughlings Jackson. But the relationship to the anatomy of the spinal cord in the rabbit would not puzzle me so much if the knee-jerk were invariably abolished in lobar pneumonia—which, of course, is very far from the case. I was stimulated to pay special attention to this feature through a clinical lecture by the late Samuel West, who mentioned that abolition of the knee-jerk might be a valuable diagnostic aid in distinguishing acute thoracic disease from acute abdominal conditions. During the late war the concentration of material upon a very large scale afforded an opportunity for intensive investigation. The state of the knee-jerks was noted at all stages of the 558 cases of lobar pneumonia which came under my care, and since the war the series has been extended to approximately one thousand with the following results.

The knee-jerks were abolished (in the early days of the illness) in 23·7 per cent. cases. They were feebly elicited bacilli (T.C.D.) isolated from swabs showing morphological diphtheria bacilli (i.e., the total of both virulent and avirulent bacilli) after inoculation than before (Table IIIA, p. 41 of the report) and especially during the years 1930 to 1933, is a factor which cannot be overlooked. As shown by the report, the true proportion of virulent diphtheria bacilli before inoculation is a matter of inference.

(3) The use of a chocolate tellurite medium in 1932–33 for the isolation of colonies. H. J. Parish has pointed out (see THE LANCET, 1934, ii., 1192), and this is confirmed by Prof. Hedley Wright, that the use of this medium considerably increases the proportion of positive results—possibly by 25 per cent.

Valuable as the experience of the school is, I consider that it cannot be regarded as the basis of a belief that carrier-rates are increased following upon immunisation. The Liverpool evidence to the contrary is far from complete but is suggestive; thus in one school of 200–300 children a considerable number of swabs taken some years after the completion of inoculation were all negative.

On the other hand the evidence that *gravis* infections give rise to very high carrier-rates is very strong. A recent experience in a 48-bedded scarlet fever block showed an incidence of 25 carriers of virulent organisms among 45 swabbed; the children in one of the two wards were almost all carriers, whether inoculated or not and whether Schick-positive or not. Only one case of diphtheria arose; the source of infection was probably a nasal case as has so often been our experience. This gives a total carrier-rate of 55 per cent., a figure even higher than those quoted by Surgeon-Captain Dudley. This outbreak of carriers, which I hope will shortly be published, emphasises the second point of my letter of March 23rd—namely, that there is much evidence that carriers are less common sources of infection of cases than are the cases themselves.

I am, Sir, yours faithfully,

Liverpool, April 25th. C. O. STALLYBRASS.

CONTINUOUS DRIP BLOOD TRANSFUSION

To the Editor of THE LANCET

SIR,—I have read with great interest the article by Dr. Marriott and Dr. Kekwick in THE LANCET of to-day. In the position of house surgeon I have seen the almost miraculous results of continuous drip intravenous infusion of glucose-saline, and at that time wondered why my chiefs had not the foresight to employ whole blood in doses calculated to increase the hæmoglobin percentage to an appreciable extent.

Two points in technique have seemed to me of practical value. At the Royal Southern Hospital, Liverpool, a very neat reservoir is employed for the solutions infused. It consists of a vacuum flask, which may be of any size, with an inverted U-tube fixed to the outer cover, one end dipping into the interior, and the other end terminating in a tap and nozzle. A rubber bulb communicates by a side tube with the top of the U-tube to set the syphon in action. Another detail of even greater use is the drip bulb. The air in the upper part of the bulb tends in a little time to become absorbed by the fluid, until the level of the fluid rises up to the nozzle and the rate of flow can no longer be controlled. This is best countered by a side tube attached to the upper portion of the drip chamber and closed by a tap, a second tap of course controlling the rate of flow proximal to the nozzle. When the fluid level rises too high the flow must be turned off at the upper tap and the side tap opened to allow the fluid to fall to the requisite level.

I heartily agree with the open method of approach to the vein recommended. Plain needles and more specialised needles can be inserted by skin puncture—in expert hands. But even these hands occasionally fail to reach the vein on the first attempt, and repeated attempts in an unanæsthetised—and usually desperately ill—patient are acutely distressing if not dangerous. Moreover, the intima of the vein is so easily traumatised by a pointed object in its lumen that the subsequent infusion may be very slow or may even cease altogether.

No reference was made in the article to the reactionary rigors and even more dangerous constitutional signs which rarely accompany even the relatively minute dosage commonly employed in transfusions. It would be very interesting to hear the divergent views on the question of increased risk with this otherwise more rational dosage. I feel that in transfusion the surgeon has a most potent weapon with a wide and ever-widening range of usefulness.

I am, Sir, yours faithfully,

Liverpool, April 26th. J. GARNETT SHELDON.

SO-CALLED ACIDOSIS ATTACKS

To the Editor of THE LANCET

SIR,—Dr. Paterson's article will, I hope, evoke the discussion that it deserves. The problem at issue is, I believe, really more complicated than is envisaged by him and the authors from whose writings he quotes. I am in agreement with him that a disturbance of hepatic function is immediately responsible for the symptoms of cyclical vomiting, and that such a disturbance occurs also in many so-called allergic conditions, such as migraine, urticaria, angioneurotic œdema, certain forms of eczema, the eczema-prurigo syndrome of Besnier, and in some cases of asthma. This was clearly shown by Oriel in your own columns (1928, ii., 1009, 1064), and can be confirmed by anyone who will collect specimens of urine at different times throughout the 24 hours from a patient during an active period of his symptoms. In a characteristic case it will be found that in the period preceding the active paroxysm and during its early stages the urine is scanty, concentrated, highly acid, loaded with urates, and contains an excess of urobilin and a diminished quantity of chloride; after the paroxysm there is a diuresis, the urine becoming dilute and neutral or even alkaline, and the retained chloride is excreted. This phenomenon illustrates the futility of examining one specimen of urine in these cases.

It will be observed that in the condition under discussion, as well as in many others such as gout, there is preceding and during the period of active symptoms retention of fluid and mineral salts, particularly sodium chloride, and that in the post-paroxysmal period the retained fluid and minerals are excreted. The mobilisation and localisation of the retained fluid determine the particular symptoms or group of symptoms to which a given patient is liable. Thus in urticaria mobilisation of fluid occurs in the dermis, in angioneurotic œdema in the subcutaneous tissue, in eczema and prurigo in the epidermis and papillæ, in migraine and probably in epilepsy in the brain, and so on. This conception, which has been fully discussed in all its aspects by E. Földes (A New Approach to Dietetic Therapy, Boston, 1933), is of great practical importance because, no matter what the factors leading to retention may be in the individual case, one can control the tendency to a great extent by dietetic measures. The antiretentional type of dietary, advocated by Földes, corresponds closely with that which I have for many years advised (THE LANCET,

OBITUARY

SIR RICHARD STAWELL, K.B.E., M.D.Melb.

WE briefly announced last week the death in his seventy-second year of Sir Richard Stawell, almost on the eve of the annual meeting of the British Medical Association at which he was to preside. The son of Sir William Foster Stawell, chief justice of Victoria, Richard Rawdon Stawell was born in Melbourne and spent the whole of his life there, except for a brief period when he was sent to England to be educated at Marlborough. He came of well-established Irish stock, for his grandfather was Jonas Stawell of Old Court in the county of Cork, who married the daughter of William Foster, bishop of Clogher. He took his first medical qualification in 1887 from Trinity College, Melbourne, and after holding resident posts did further study in Europe and America, obtaining the D.P.H. in 1891. Shortly after his return to Victoria he was appointed to the Melbourne Children's Hospital and remained for 17 years an active member of the staff. The year 1902 began his association with the Melbourne Hospital and this lasted more than 20 years, for the greater part of which he was a member of the management committee and chairman of the house committee. After reaching the retiring age he was elected president of the hospital. To him was largely due the inauguration of systematic clinical teaching at the hospital, and one of his colleagues has put on record his appreciation of Stawell's supreme devotion to the cause of medical teaching, sparing neither time nor energy to further his object. He was a born teacher and the scientific grounding in physical signs and in neurological diagnosis which he gave his students was something never to be forgotten. Although often smarting from some well-merited rebuke, the recipient ultimately came to regard this apparently austere clinician with feelings of real affection. The idea of an Australasian Association of Physicians arose in Melbourne, and it was Stawell's aim that this body should run on lines similar to those of the sister association in this country. He was himself elected its first president. During the war he served with the third Australian General Hospital with the rank of lieutenant-colonel A.A.M.S., and became later a member of the medical advisory committee to the repatriation department of the Commonwealth. In 1929 he was created K.B.E. Sir Richard Stawell married in 1908 and leaves three children, a son and two daughters.

HUMPHRY JOHN WHEELER, M.D.Durh.

Dr. Wheeler, who died in London on April 2nd, was born in 1865 at High Wycombe, the only child by his second marriage of the late Mr. Thomas Wheeler, a banker and brewer in that town. The family was an old-established one which had done much by fostering the chair-making industry to raise the town to its present position in the industrial world. Dr. Wheeler received his medical education at St. George's Hospital and the Durham medical school at Newcastle-upon-Tyne, qualifying with the double English diploma and the M.B. Durh. in 1887. He was house surgeon at St. George's and proceeded to the M.D. Durh. in 1889. After a period of post-graduate work in Paris he returned to his native town where he practised for over 30 years, retiring in 1913. In the following year, on the outbreak of war, he joined the 13th London Regiment (territorial) as medical officer and at the conclusion of hostilities received for a further nine years an appointment under the Ministry of Pensions. He was consulting medical officer to the High Wycombe War Memorial Hospital. Dr. Wheeler married in 1892 Augusta, the eldest daughter of the late Mr. G. D. Bushe, of the Four Courts, Dublin, who survives him, with one daughter who is married to Squadron Leader F. R. Alford, M.C., R.A.F.

FRANK WINSON RAMSAY, M.D., M.S. Durh., F.R.C.S. Edin.

Mr. F. W. Ramsay, who died at Bournemouth on April 25th in his 73rd year, was educated at Aske Grammar School and at Montmorency, near Paris. He studied medicine at Newcastle-upon-Tyne, and while a student captained the Durham University football club and the Northumberland Rugby football team. He was tall, with exceptional physique and great physical strength. After qualifying in 1886 he was resident medical and surgical assistant at Newcastle Royal Infirmary, and next year started practice at Winton, near Bournemouth. He took the D.P.H. and became medical officer of health. His public work at Winton included the chairmanship of the Parish Council, membership of the Hampshire County Council, and of the Board of Guardians. He also held the office (now extinct) of way warden and was major in the 4th (Volunteer) Hants Regiment which he was asked to command. In 1893, after taking the M.S. Durh. with 1st class honours, and the F.R.C.S.Edin., he was appointed hon. surgeon to Victoria Hospital, Bournemouth, and gradually as his surgical work increased he gave up general practice and devoted himself to surgery alone. His active association with the hospital lasted 32 years, and four years ago he became chairman of the board of management, a post which he held until his death. He was also at various times surgeon to the St. Mary's Home for Invalid Ladies, the National Sanatorium for Diseases of the Chest, the Children's Hospital, Swanage, and a number of cottage hospitals in the neighbourhood. During the war he was in charge of a hospital at St. Malo. When the British Medical Association proposed to meet at Bournemouth in 1934 it was natural that he should be asked to preside, but before the meeting was held he decided that his health was not good enough for such a strain.

[*Photograph by Debenham and Gould*

MR. F. W. RAMSAY

A colleague who first met him just after he had realised his ambition to begin surgical work in what was then a small country hospital says that Ramsay held the same ideals right through his great surgical activities. The surgeon of even such a small hospital ought, he held, to be fully prepared to deal with every sort of surgical emergency that might occur in 12·5 per cent. cases. They were present to a degree which might be described as normal in 45 per cent. cases, and in 18·8 per cent. they were distinctly exaggerated.

It is clear, therefore, that whilst an absent knee-jerk might just turn the scale in favour of diagnosing a thoracic lesion, its presence will certainly not exclude pneumonia.

To whom is the credit due for identifying the occasional temporary abolition of the knee-jerk in pneumonia? Was it in fact Hughlings Jackson? Incidentally, one cannot help supposing that the original observation must have been at a time when it was not customary to employ the now familiar "hammer" without which a considerable number of sluggish and even normal knee-jerks might be overlooked.—I am, Sir, yours faithfully,

Brook-street, W., April 27th. ADOLPHE ABRAHAMS.

MATERNAL MORTALITY

To the Editor of THE LANCET

SIR,—I read with interest Mr. Eardley Holland's paper on maternal mortality, and I do not think his scheme of drafting specially trained men into general practice is a good one for the following reasons:—

(1) For an obstetrician to be sufficiently skilful to deal with serious complications he must be constantly handling abnormal cases. This he could not do if he were in general practice. (2) A man specially trained in obstetrics and possessing a diploma of the British College of Obstetricians and Gynæcologists will consider himself a specialist, and will probably have more confidence than his skill and experience justifies. He will be loth to call in a consultant, and his patients, knowing his qualifications, will not expect him to do so. (3) These men, having spent their early graduate years at obstetrics, will probably have an indifferent knowledge of medicine and surgery, the practice of which constitutes 80–90 per cent. of a practitioner's work.

In our endeavour to reduce maternal mortality we must not lose sight of the fact that it is just as great a tragedy for a young person to die as a result of an undiagnosed empyema or abdominal emergency as it is for a woman to die in childbirth. I think the appointment in each area of really good obstetrical consultants, who could be called upon to deliver or advise upon difficult cases, would greatly raise the standard of midwifery. The educational value to the practitioner would be considerable, and the public would expect a consultant to be called if conditions became complicated, just as they expect a surgeon to be called when serious surgical conditions arise. I am, Sir, yours faithfully,

Cheadle Hulme, April 29th. NICHOLAS CRAIG.

DOSAGE OF ASCORBIC ACID

To the Editor of THE LANCET

SIR,—I should be glad if you would allow me to correct a misstatement in your otherwise excellent annotation (p. 999). In my letter which you published on March 23rd I credited Dr. Bell with being the first to publish a case of infantile scurvy treated with synthetic vitamin C, but did not wish to imply that I had also used a synthetic preparation. My experience has been confined to ascorbic acid isolated from natural sources, as regards the treatment of both scurvy and cœliac disease.

I am, Sir, yours faithfully,

London, W., April 28th. WILFRID SHELDON.

THE WORD INSULIN

To the Editor of THE LANCET

SIR,—Having read with great interest the obituary notice of Sir Edward Sharpey-Schafer in your issue of April 6th I think that it might interest your readers to be reminded that it was Sharpey-Schafer who first made the name "insuline" generally accepted as designation for the autacoid of the islet tissue (the "Endocrine Organs," 1916, p. 128). The name had been suggested before by J. de Meyer of Brussels in 1909, and was adopted in 1922 by Banting and Best when they had succeeded in perfecting the method of pancreas extraction to such a degree that insulin could be used in practice. But Sharpey-Schafer tells us, in a footnote to the 1925 edition of his book, he had not seen de Meyer's suggestion when he made his.

I am, Sir, yours faithfully,

F. W. FORNET,

April 19th. Institute of Microbiology, Saarbruecken.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. S. K. Foster to *Pegasus*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt.-Cmdr. G. F. Abercrombie to *Barham*.

Surg. Lt. J. O. Clyde promoted to Surg. Lt.-Cmdr.

Surg. Lt. J. F. Corr transferred from List 1 of Mersey Divn. to List 2 of Severn Divn.

Surg. Lts. D. M. Dean to *Furious*, and C. M. Lamont to *Drake* for R.N. Hospital, Plymouth.

ROYAL ARMY MEDICAL CORPS

Short Service Commissions: The undermentioned Lts. (on prob.) are restd. to the estabt.: I. U. Young, A. MacLennan, and J. O'Connell.

SUPPLEMENTARY RESERVE OF OFFICERS

Lt. J. A. Brocklebank, from Supp. Res. of Off., R. Signals, to be Capt.

TERRITORIAL ARMY

Capt. N. Moulson resigns his commn.

W. N. S. Donaldson to be Lt.

ROYAL AIR FORCE

Flight Lt. T. D. L. Bolan is granted a permanent commission in this rank.

RESERVE OF AIR FORCE OFFICERS

Flight Lt. J. E. Foran relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE

Majs. to be Lt.-Cols.: E. C. A. Smith, A. Y. Dabholkar, M.C., K. S. Master, M.C., S. R. Prall, R. N. Khosla, S. A. McSwiney, and H. S. Rajan.

The undermentioned officers retire: Lt.-Cols. J. McG. Skinner and J. B. Lapsley, M.C.

DEATHS IN THE SERVICES

The death occurred at Southsea on April 30th of Colonel Richard Jennings, C.B.E., M.D., late A.M.S. He was born in January, 1856, and was educated at the Royal University of Ireland, qualifying M.D., M.Ch. R.U.I. in 1878. He entered the Army as a surgeon in February, 1881, became Major in 1893, Lt.-Col. in 1901, Colonel in December, 1908, and retired in January, 1913. He took part in the South African War 1900–1902, was twice mentioned in despatches, and was awarded the Queen's medal with three clasps and the King's medal with two clasps. In 1911 he was appointed K.H.S., and in 1919 was created C.B.E. (Mil.). He married in 1898 Mabel (d. 1919), daughter of Mr. J. Borthwick Paterson.

OBITUARY

SIR RICHARD STAWELL, K.B.E., M.D.Melb.

We briefly announced last week the death in his seventy-second year of Sir Richard Stawell, almost on the eve of the annual meeting of the British Medical Association at which he was to preside. When the British Medical Association proposed to meet at Bournemouth in 1934 it was natural that he should be asked to preside, but before the meeting was held he decided that his health was not good enough for such a strain.

[*Photograph by Debenham and Gould*

MR. F. W. RAMSAY

A colleague who first met him just after he had realised his ambition to begin surgical work in what was then a small country hospital says that Ramsay held the same ideals right through his great surgical activities. The surgeon of even such a small hospital ought, he held, to be fully prepared to deal with every sort of surgical emergency that might occur in the town in which he lived. If the art of surgery had progressed elsewhere, through the thoughtful development of existing methods and of new ideas of procedure, it was allowable to hope that some progress might be made by those practising their art in Bournemouth as it then was. These ideals have been fully realised, and the provincial hospital of 50 beds is now the Royal Victoria and West Hants Hospital with 280 beds. Ramsay's services were sought for over much of Hampshire and Dorset, where his opinion was considered decisive on all those aspects of surgery of which his great experience had made him master. Of the many surgical instruments he invented the best known are his uterine hollow dilators, but he also devised useful forms of vulsellum forceps, flushing curettes, broad ligament clamps, and vaginal hysterectomy needles.

The following notes on Ramsay's surgical procedures show the character of his work. A method of nephrorrhaphy for floating kidney goes by his name. In procidentia in elderly persons he did a subtotal hysterectomy, then sutured the stump into the lower end of the abdominal wound, transfixing the stump with a strip of live fascia. Perforated gastric ulcer he treated by bringing the ulcerating area up to the abdominal wound to which he sutured it. He then introduced a rubber catheter downwards towards the duodenum, so as to feed his patient at once with peptonised foods and fluids. The catheter he left in six weeks. For fractured patella he drilled each fragment horizontally and threaded them with silver wires which he approximated by firmly twisting in opposite directions—a method afterwards called by another name. In the radical cure for hernia he used a slip of live fascia from the external rectus to close the opening, its blood-supply being carefully preserved at the basal end. Acute hæmorrhagic pancreatitis he treated by drainage.

A pioneer motorist, and a founder member of Royal Automobile Club, Mr. Ramsay was chairman of the central committee of the Hampshire Automobile Club. He spent his holidays motoring in continental countries. At home he was keenly interested in his garden and in bird and animal life. His daughter, Dr. Olive Ramsay, to whom we owe many of these details, holds several hospital appointments in Bournemouth.

Dr. G. B. SILVER DARTER, who died at Kenilworth, Capetown, on March 21st after a long illness, was a St. Thomas's student and qualified M.B., B.S. Durh. in 1889. In the following year he married Miss Lilian K. Morris, a member of a well-known Berkshire family, and returned to South Africa where he was born and brought up. For reasons of health he settled in the Karoo, becoming medical officer of health for Victoria West. But he occupied important positions in Cape Colony, being chairman of the Board of Executors, director of the Good Hope Savings Bank, and chairman of the Union National and General Assurance Co. He is survived by his widow.

MEDICAL NEWS

Royal College of Physicians of London

At a comitia held on April 25th, with Lord Dawson of Penn, the president, in the chair, the following were elected to the fellowship:—

Sir Robert Muir, M.D. Edin. (Glasgow); Jonathan Campbell Meakins, M.D. McGill (Quebec); Hazel Haward Chodak Gregory, M.D. Lond. (London); Alfred Douglas Bigland, M.D. Liverp. (Liverpool); Hugh Hadfield Carleton, M.D. Oxon. (Bristol); Reginald Hugh Simpson, M.D. Lond. (London); Colonel John Heatley-Spencer, M.D. Lond. (A.M.S. London); Stuart Jasper Cowell, M.B. Camb. (London); Christoph [illegible] M.D. Lond. (London); Major George I [illegible] Aberd., I.M.S. (Madras); Alexander [illegible] (London); Philip Cyril Powter Cloake, [illegible] ham); Keith Douglas Fairley, M.D. Mell [illegible] [illegible], M.D. Glasg. (Glas [illegible] ll); Robert Platt, M [illegible] William Fielding Addey, [illegible], M.D. Lond. [illegible] D.M. Oxon. (London); James [illegible] n); William Moses Feldman, M.D. Lond. (London); Alexander Macdougall Cooke, D.M. Oxon. (Oxford); Edward Rowan Boland (London); John Alexander Charles, M.D. Durh. (Newcastle-on-Tyne); William Evans, M.D. Lond. (London); Thomas Cecil Hunt, D.M. Oxon. (London); Henry Yellowlees, M.D. Glasg. (London); and Robert Alexander McCance, M.D. Camb. (London).

The following were admitted members of the College:—

Francis Ray Bettley, M.B. Lond.; Cyril Robert Birnie, M.B. Lond.; Simon Redvers Bray, M.B. Melb.; Anthony Caplan, M.B. Lond.; Olive Mary Capper-Johnson, B.M. Oxon.; Mohammed Fathi El-Seifi, M.B. Cairo; Ernest Hywel Evans, M.B. Wales; Philip Rainsford Evans, M.B. Manch; Gordon Wilkinson Goodhart, M.D. Camb.; George Bruce Hall, M.B. Sydney; Howard Bluntisham Hodson, M.D. Lond.; John Macdonald Holmes, M.B. Leeds; Terence Graham Faulkner Hudson, M.B. Lond.; George Norman Myers, M.D. Durh.; Bernard Clive Nicholson, M.B. Camb.; Ronald Sherrington Ogborn, M.B. Lond.; John Hammond Palmer, M.D. McGill; Denis Adrian Pritchard, Surg.-Comdr., M.B. Sydney; Edward George Sayers, M.B. N.Z.; Eric Frank Scowen, M.D. Lond.; Joel Nathan Strauss, M.B. Manch.; and Edward James Starbuck Woolley, M.B. Lond.

Licences were conferred upon 103 candidates (94 men and 9 women) who have passed the final examination of the Conjoint Board and have complied with the by-laws of the College. The following are the names and medical schools of the successful candidates:—

B. Agranat, Guy's; I. J. Amorin, Manch.; A. W. H. Ashbery, Birm.; A. C. Ashton, Manch.; E. C. Atkinson, St. Bart.'s; L. J. Bacon, Camb. and St. Bart.'s; P. N. Bardhan, Singapore; A. J. E. Barlow, Leeds; A. H. Barwell, St. George's; S. M. Basu, Rangoon; P. W. G. Baxter, Guy's; T. L. S. Baynes, St. Bart.'s; B. P. Bhattacharjya, Patna and Manchester; Beatrice A. Blake, Royal Free; P. I. Boyd, Univ. Coll; T. M. Boyle, Leeds; Kathleen G. Brimelow, Bristol; A. S. Bullough, and W. P. Cargill, Manch.; R. S. Carpenter, Lond.; J. N. Cave, Camb. and St. Thomas's; A. E. Cohen, Camb. and Lond.; J. L. Collis, Birm.; W. T. Cooke, Camb. and Birm.; J. S. Cookson, Camb. and St. Bart.'s; R. W. Cope, Guy's; L. M. Curtiss, St. Bart.'s; J. V. Dacie, King's Coll.; G. C. Dansey-Browning, St. Thomas's; R. B. Davis, Camb. and Lond.; A. R. O. Denton, Guy's; G. W. N. Dunn, Camb. and St. Bart.'s; E. H. Evans and W. E. F. Evans, St. Bart.'s; Barbara J. Fisk, Margaret FitzHerbert, Evelyn J. Forgan, and Sheila M. Franklin, Royal Free; A. H. T. F. Fullerton, Camb. and Birm.; L. R. Gardner, Camb. and Middlesex; E. Garch, Guy's; R. J. Gilpin, King's Coll.; S. Ginsberg, St. George's; C. Hardwick, Camb. and Middlesex; A. Harris, Manch.; J. R. G. Harris, Camb. and Lond.; A. J. Helfet, Cape and Liverp.; A. T. Hunt, Univ. Coll.; M. Hynes, Camb. and Middlesex; F. J. G. Jefferiss, St. Mary's; A. E. Jowett, Bristol; R. Kauntze, Camb. and St. George's; E. L. Kirstein and A. M. Lasnick, Univ. Coll.; D. C. Lavender, Camb. [illegible] Lawrence, Univ. Coll.; H. T. Laycock, [illegible] V. Lewis, St. Mary's; J. J. Lichterma[illegible] Liverp. and Middlesex; P. S. Luffman, [illegible] Lytton, Camb. and Univ. Coll.; A. B. Marshall, Leeds; Bertha Marston, Birm.; F. R. R. Martin, Camb. and Leeds; R. L. Mehra, Punjab and Lond.; A. G. H. Menzies, Liverp.; L. Millward, Liverp.; W. T. M. Moar, Lond.; R. L. Moody, St. Thomas's; S. H. Navidi, Bombay and West Lond.; J. G. Nel, Wits'rand and St. Bart.'s; D. A. O'Reilly, St. Thomas's; J. F. Paterson, Camb. and St. Bart.'s; J. B. Phillips, Cardiff; E. E. Pochin, Camb. and Univ. Coll.; G. Pollack, St. Mary's; P. Ramchan[illegible]; B. Reeves, Lond.; J. Revans, [illegible] Liverp.; J. R. Rose, Camb. [illegible] Samson, Cape and Lond.; C. W. A. Searle, Camb. and King's Coll.; A. Shapiro, Univ. Coll.; H. S. Sharp, Camb. and St. Thomas's; B. J. Shaw and R. A. Shove, Birm.; P. N. Shutte, St. Thomas's; A. H. M. Siddons, Camb. and St. George's; G. R. Taylor, St. Bart.'s; J. W. Todd, Middlesex; Mary R. Thompson and W. F. Viret, Leeds; A. A. Waller, Guy's; T. J. Walters, Cardiff and St. Mary's; F. G. Ward, St. Bart.'s; P. J. Wenger-Byrne, Charin[illegible] Whitestone, Univ. Coll; S. R. F. Whitt[illegible] Coll.; A. G. M. Wilson, Birm.; E. B. [illegible]; and N. R. Wyndham, Sydney.

Diplomas in tropical medicine and hygiene were conferred jointly with the Royal College of Surgeons upon the following candidates:—

D. S. Abeyagunawardene, J. C. Anders, G. F. Bartholomeusz, S. M. Basu, G. B. Beckner, F. Bell, S. Y. Chao, L. S. L. de la Harpe, G. A. Dragatsi, F. W. Farrar, I. J. Fernando, K. M. Fozdar, F. N. Grannum, T. I. Ibrahim, A. Lucas, R. B. Mehta, B. Patnaik, W. M. Quin, M. J. A. Sandrasagra, O. S. Sela, A. E. Stevens, R. L. Tiruchelvam, H. G. H. Waters, Enid M. O. Will, and W. R. Williams.

Sir Edmund Spriggs will deliver the Croonian lectures on May 14th, 16th, and 21st at 5 P.M., his title being a Clinical Study of Headaches.

Royal College of Surgeons of England

A meeting of the council of the College was held on April 25th with Sir Holburt Waring, the president, in the chair for the first time since his return from Australia, where he opened the new building of the Royal Australasian College of Surgeons. It was decided that the subject for the Jacksonian prize essay for the year 1936 should be hydronephrosis. An offer by Sir Matthew Thompson to present to the College a portrait by him of Sir D'Arcy Power, the honorary librarian, was accepted.

The following hospital appointments were approved for the six months' post required of candidates before admission to the final examination for the fellowship: Royal Infirmary, Halifax, resident surgical officer and first house surgeon; and Metropolitan Hospital, London, senior house surgeon.

The council agreed to the suggestions of the Robert Jones memorial fund committee for the foundation of a Robert Jones professorship of the Royal College of Surgeons of England for an annual lecture or lectures on some subject connected with orthopædic surgery (sum allocated £1000); and for the foundation of a travelling research fellowship to be awarded alternately by the University of Liverpool and the Liverpool Medical Institution jointly; and the Royal College of Surgeons of England. The sum of £1000 was allocated for the professorship and £2000 for the travelling research fellowship.

Sir Holburt Waring was nominated as the representative of the College to serve on the National Council for the Disposition of the Dead. The date of the reception to be given for the International Neurological Congress was fixed for Tuesday, July 30th.

William Thomas Gordon Pugh and Henry Edmund Gaskin Boyle, members of twenty years' standing, were elected to the fellowship of the College. A diploma of fellowship was granted to Frederick Ronald Edwards and diplomas in tropical medicine and hygiene were granted jointly with the Royal College of Physicians to the candidates mentioned above.

Society of Apothecaries of London

At recent examinations the following candidates were successful:—

Surgery.—M. Belo-Zercovsky, London Hosp.; A. E. Hassan, Univ. of Birm.; K. P. Pauli, Univ. of Bristol; J. Richter, St. Mary's Hosp.; L. E. Sealy, Univ. of Bristol; and H. M. R. Waddell, Univ. of Manch. and Charing Cross Hosp.

Medicine.—J. H. Bentley, Univ. of Camb. and Middlesex Hosp.; F. W. Treadwell, Univ. of Birm.; J. F. L. Walley, Univ. of Camb. and St. Mary's Hosp.; W. C. Winterbottom, St. Mary's Hosp.; and J. L. Wredden, London Hosp.

Forensic Medicine.—J. H. Bentley, Univ. of Camb. and Middlesex Hosp.; F. H. Holder, Univ. of Manch.; R. G. Joyce, St. Bart.'s Hosp.; N. O. Lucas, Guy's Hosp.; K. P. Pauli, Univ. of Bristol; A. Ponder, Guy's Hosp.; J. F. L. Walley, Univ. of Camb. and St. Mary's Hosp.; and J. L. Wredden, London Hosp.

Midwifery.—B. M. Jensen, Univ. of Liverp.; P. D. Lynch, Guy's Hosp.; and G. M. Williams, London Hosp.

The following candidates, having completed the final examination, are granted the diploma of the society entitling them to practise medicine, surgery, and midwifery: M. Belo-Zercovsky, J. H. Bentley, A. E. Hassan, J. Richter, J. F. L. Walley, and W. C. Winterbottom.

University of London

At recent examinations David Prentice obtained the post-graduate diploma in psychological medicine with special knowledge of psychiatry, and D. S. Clark with special knowledge of mental deficiency.

On May 7th and 14th, at 5 P.M., in the physiology theatre of University College, Gower-street, W.C., Dr. E. W. Fish will lecture on the physiology of teeth. On Mondays, from May 13th, at the same hour and place, Dr. D. H. K. Lee will give four lectures on the physiological effects of tropical climate. These lectures are open to all interested.

University of Edinburgh

Dr. M. M'Nair Murray and Dr. W. C. Wilson have been appointed part-time lecturers in the department of child life and health. Dr. W. G. Millar has been appointed lecturer on morbid anatomy in succession to Dr. James Davidson, and Dr. R. F. Ogilvie, lecturer in the department of pathology. Dr. J. D. Comrie, senior lecturer in the faculty of medicine, has been elected a member of the faculty and of the senatus.

British College of Obstetricians and Gynæcologists

The quarterly meeting of the council was held on April 27th, when Dr. J. S. Fairbairn, the president, who was in the chair, formally admitted to the fellowship,

William Robert Addis (Manchester), Dugald Baird (Glasgow), Alice Bloomfield (London), John Chisholm (Sheffield), Alfred Benthin Danby (Birmingham), *Edward Kirkpatrick MacLellan (Nova Scotia), and Edward Lawton Moss (London).

The following were elected to the fellowship, but have not yet been formally admitted:—

Leighton Carling Conn (Alberta), Amy Margaret Fleming (London), Arthur Alexander Gemmell (Liverpool), Victor John Frederick Lack (London), William Collis Spackman (Bombay), and Leslie Williams (London).

The following were admitted to the membership:—

Josiah Grant Bonnin, David McKay Hart, Kenneth Alfred Knight Hudson, *Benjamin Dunning Knoblauch, *Robert MacKenzie Honey, Ronald Wallace Knowlton, John Laing Mewton, Hugh James McCurrich, Ronald Hodgson Nattrass, *Ossian Robertson, Helen Elizabeth Rodway, Margaret Rorke, Francis Edward Stabler, John Arthur Stallworthy, David Michael Stern, Hugh Stirling, and *Muriel Stowe.

* In absentia.

Ronald McRobert (India) was elected to the membership.

At the annual general meeting which followed, Mr. Aleck Bourne, Prof. James Hendry, Sir Ewen J. Maclean, and Prof. M. H. Phillips were elected to the council as representatives of the fellows, and Dr. W. C. Armstrong and Dr. C. P. Brentnall as representatives of the members. The report of the Joint Council of Midwifery was considered and generally approved, but some aspects of the scheme were reserved for further consideration.

On April 26th a reception was held in the College House, when Lady Simson presented to the College the collection of books purchased as a memorial to her husband the late Sir Henry Simson.

Queen's University of Belfast

The senate have appointed Dr. Henry Barcroft to the Dunville professorship of physiology.

Dr. Barcroft, who is 30 years of age, is the elder son of Prof. Barcroft, of Cambridge. He was educated at Marlborough and King's College, Cambridge, and qualified from St. Mary's Hospital, London, in 1932. In the following year he graduated as B.Chir. Camb., and was appointed lecturer in physiology at University College. His physiological investigations, which began at Cambridge before he took up medical work, have been concerned with the mechanics of the circulation, and are recorded in the *Journal of Physiology*.

Mr. D. C. Harrison, D.Sc. Lond., has been appointed to the White chair of biochemistry. He is at present lecturer in that subject in the University of Sheffield.

Jubilee Commemoration in New Zealand

The New Zealand Jubilee gift to the King is to be a fund for cancer research in the Dominion. It will be administered by the New Zealand branch of the British Empire Cancer Campaign, and the government will contribute £5000.

Fellowship of Medicine and Post-Graduate Medical Association

Courses in thoracic surgery will be given at the Brompton Hospital (May 13th to 18th); in proctology at the Gordon Hospital (May 20th to 25th); in gynæcology at the Chelsea Hospital for Women (May 27th to June 8th); in chest diseases at the Victoria Park Hospital (May 27th to June 1st); in venereal diseases at the London Lock Hospital (May 27th to June 22nd); in obstetrics at the City of London Maternity Hospital (May 25th and 26th); and in infectious diseases at the Park Hospital, Hither Green (June 15th and 16th). Other arrangements include: an M.R.C.P. course in chest diseases at the Brompton Hospital, during June; a clinical and pathological course, on Tuesdays and Thursdays at 8 P.M., at the National Temperance Hospital (June 11th to 27th); and an M.R.C.P. course at the Victoria Park Hospital, dealing with heart and lungs (June 5th to 21st), at 6.30 P.M., on Wednesdays and Fridays. A panel of teachers gives daily clinical instruction in various branches of medicine and surgery. A supper-dance and cabaret has been arranged to take place at Claridge's on Wednesday, June 5th, at 9.30 P.M. The dance is open to all members of the medical profession, and tickets can be obtained from the secretary of the fellowship, 1, Wimpole-street, London, W.1.

The annual dinner of the Royal Medico-Psychological Association will take place at Claridge's Hotel, London, on Wednesday, July 3rd.

Harveian Society of London

The Buckston Browne annual banquet of this society will be held at Merchant Taylors' Hall, Threadneedle-street, E.C., on Thursday, June 13th, at 7.30 for 8 P.M.

Middlesex Hospital Rebuilding

The west wing of the new Middlesex Hospital building of which the Duke of York laid the foundation-stone in June, 1928, will be declared open by the Duke and Duchess of York on Wednesday, May 29th, at 3 P.M.

Royal London Ophthalmic Hospital

The Duke and Duchess of York are opening the new block of buildings at Moorfields on May 16th. The King has consented to the new block being known as the King George V. extension. It has cost £113,000, and only £12,500 remains to be raised. An anonymous donor has promised to give £4500 if the balance of £8000 is raised by the end of June.

Hospitals and Road Accidents

In the Hospitals Year Book for 1935, reviewed in our annotations columns last week, the Central Bureau of Hospital Information gives an estimate that 25,000 victims of road accidents were treated in the voluntary hospitals of Great Britain and Ireland during 1934. The total cost incurred was £235,000, of which £110,000 was recovered by the hospitals, £30,000 from the patients or their friends, and £80,000 under the Road Traffic Acts and common law. In 1927, out of £230,000 only £26,000 was recovered.

Rockefeller Medical Fellowships

The Rockefeller medical fellowships for 1935-36 will shortly be awarded by the Medical Research Council. The value of these fellowships will be not less than £350, exclusive of allowances, and they are given in accordance with the desire of the Rockefeller Foundation to graduates who have had some training in research work in the primary sciences of medicine, or in clinical medicine or surgery, and are likely to profit by a period of work at a university or other chosen centre in the United States or on the continent before taking up positions for high teaching or research in the British Isles. Further particulars are obtainable from the secretary of the Council, 38, Old Queen-street, Westminster, S.W.1. Applications must be made by June 1st.

New Baths at Woodhall Spa

In several directions there are signs of fresh developments at the British spas. The past week has witnessed the opening of a new clinic for rheumatism, and a meeting of the British Health Resorts Association at Buxton, whilst Princess Marie Louise on April 27th laid the foundation-stone of a new bath establishment at Woodhall Spa in Lincolnshire. The "bromo-iodine salt waters" at Woodhall are derived from a shaft sunk for coal in the early years of last century. They come from strata about one hundred feet below sea level, and are hypertonic with sodium and calcium chlorides and contain also about twenty-four and fifty parts per million of iodine and bromine. The palmy days of Woodhall dated from the erection of the existing baths in 1887, but after the war the place, like some other spas, fell into neglect. An "old guard" of visitors, having knowledge of its merits, have always been faithful, however, and with recent changes of ownership a great revival of interest has taken place, under the inspiration of Sir Archibald and Lady Weigall, who have now renovated the existing baths, and added a small clinic for fango packs. They are also erecting a large new bath establishment in beautiful grounds adjoining the Petworth Hotel, which have been named the "Royal Jubilee Park" by the Princess Marie Louise. The open-air assembly at the ceremony of its foundation was attended by the chairman and members of the urban district council, a number of parliamentary and public representatives of the county, and many hundreds of residents. Mr. Geoffrey Barton, the chairman of the Woodhall Spa Advancement Association, which has been a very active and useful body, proposed a vote of thanks to the Princess, which was seconded by Dr. Leonard Boys, who said it was the happiest of his days in thirty years at Woodhall Spa. Dr. Fortescue Fox, representing the British Health Resorts Association, spoke of the great change that had come over this branch of medical practice in his time; a new *science of the health resort* had sprung into existence. The smaller spas were an essential part of a national scheme of health resorts and often obtained world-wide reputation for particular ailments. Woodhall, he thought, might concentrate especially on the relief of rheumatism by manipulation pools and fango, the effective treatment of catarrh, and inflammatory deposits in the pelvis, and the use of physical remedies for high blood pressure.

Committee against Malnutrition

As already announced, a public meeting will be held at the Conway Hall, Red Lion-square, London, W.C.1, on Thursday, May 16th, at 8 P.M., to consider especially the health and nutrition of women and children in this country. Prof. V. H. Mottram will take the chair, and the speakers will include Miss Eleanor Rathbone, M.P., Dr. Janet Vaughan, Dr. J. R. Marrack, professor of chemical pathology at the London Hospital, Mr. Joseph Needham, Sc.D., reader in biochemistry in the University of Cambridge. Tickets may be had from the hon. secretary, at 19c, Eagle-street, Holborn, W.C.1 (1*s.* each).

The committee came into existence rather more than a year ago. Its name expresses the opinion of its members that all the factors necessary for the eradication of malnourishment are now completely within the power of society; whatever degree of malnourishment may have been inevitable a century ago is now a social anomaly. Though not concerned with the measures that must be taken socially to achieve its object, it regards malnutrition as the most significant manifestation of human poverty, and it endeavours by public meetings and other means to demonstrate the facts now established scientifically. A bulletin is published every two months which is devoted to every relevant aspect of nutrition and malnutrition.

St. Mark's Hospital Centenary

The Lord Mayor presided at the centenary banquet of this hospital which was held at the Mansion House on April 25th, when an appeal was made for £60,000 for necessary extensions. Mr. H. Clifford-Turner, chairman of the appeal committee, said that is was Frederick Salmon who, a hundred years ago, conceived the idea of starting a special clinic for the treatment of cancer of the lower intestines; he set up in Aldersgate-street and there treated the poor of the City of London. His fame spread, and in 20 years he had laid the foundation-stone of St. Mark's Hospital. Now, he said, there were nearly 200 men and women knocking at the hospital door who could not be let in because they had not sufficient accommodation. A number of them were suffering from cancer of the lower intestine, which, if caught in the early stages, stood a good chance of being cured. Sir Patrick Hastings, in proposing "The Hospital," said it was the only free hospital in the world that dealt with cancer of the lower bowel. It was awful to realise that if those who were waiting to enter the hospital were kept out too long, their chances of cure were lost. Money was also required to provide proper accommodation for the nursing staff. In responding to the toast, the Lord Mayor said that Charles Dickens, than whom there was never a keener critic of charitable institutions, was a generous contributor to the hospital for 25 years. "The Centenary Appeal" was proposed by Major Colin Cooper, who said that the nature of the diseases treated had been a handicap in appealing for funds. They had no heroic incidents as had the larger hospitals, neither had they maternity wards. Cancer was bad enough, but the kind of cancer they were fighting at St. Mark's was the most terrible human affliction. When the disease was detected in its early stages the percentage of patients cured was nearly 100; at the hospital it was actually nearly 50.

Mr. R. Holland-Martin, treasurer of the hospital, replied. Sir John Barran, in proposing "The Lord Mayor," spoke of the unbroken chain of happy tradition which had associated the chief magistrate of the city with St. Mark's Hospital for 100 years. It was announced that during the evening £3443 had been collected, which, with the amount of £6070 previously collected for the building fund, made a grand total of £9513.

Chelmsford Hospital

It is announced that Mrs. J. A. Keene has given £20,000 for building extensions to this hospital. Since the death of her husband three years ago she has distributed £100,000 to various institutions and charities.

University of Dublin

Mr. Joseph Barcroft, F.R.S., professor of physiology at the University of Cambridge, has been appointed the Dr. John Mallet Purser lecturer in Trinity College, Dublin, for 1935. He will speak on the mammal before and after birth (June 25th), and on chemical conditions of mental development (June 26th). The lectures will be given in the department of physiology at 5 P.M., and will be open to all medical men and medical students.

London School of Hygiene and Tropical Medicine

The 1935–36 course of study at this school, which qualifies students to sit for the University of London diploma in public health, and covers a period of nine months' whole-time work, will begin on Sept. 30th.

An open competition will be held on June 27th and 28th for the Fishmongers' Company studentship, which carries a free place in the course. Further information may be had from the secretary of the School, Keppel-street, W.C.1.

Institute of Medical Psychology

Prof. L. J. Witts, Dr. G. W. B. James, and Mr. A. E. Webb-Johnson have been appointed to the medical advisory board of this institute (formerly the Tavistock-square Clinic). It is announced that applications for evening treatment can now be entertained, and the names of those wishing to attend the morning and afternoon sessions may also be submitted. The address of the clinic is Malet-place, London, W.C.1.

Hospital Amalgamation in Dublin

Speaking at the annual meeting of Sir Patrick Dun's Hospital last week, Dr. T. G. Moorhead, chairman of the board of governors of the hospital, referred to the proposed amalgamation of Dun's with Mercer's Hospital and the Royal City of Dublin Hospital. He said that following on negotiations between the three institutions and careful consideration a provisional plan of amalgamation had been agreed on. The dean had received the provisional approval of the Hospitals Commission. A Bill to effect the amalgamation is being drafted, and it will probably be introduced to the Dail next October.

Retirement of Dr. M. J. Nolan

At a meeting of the committee of management of Down Mental Hospital on April 20th, the chairman described the present efficiency of the hospital as a monument to Dr. Nolan's zeal and foresight. He is now relinquishing office after 42 years at Downpatrick, his final act being the inauguration of a new department for electro- and hydro-therapy and occupational treatment recently opened by the governor of Northern Ireland. Dr. Nolan began his professional life in general practice in Limerick city, but soon turned to asylum work, of which his 50 years' experience has now entitled him to the position of consulting visitor in lunacy to the Lord Chief Justice. He carries with him into retirement the good wishes of the whole service.

Royal Sanitary Institute

The annual health congress of this institute will be held at Bournemouth from July 15th to 20th under the presidency of Lord Malmesbury. Among the presidents of the sections are Dr. Thomas Carnwath (preventive medicine) and Dame Louise McIlroy (maternity and child welfare), while Dr. R. Veitch Clark presides over the conference of medical officers of health. The many subjects arranged for discussion at the congress include various aspects of venereal disease, the care of the mother in industry, the care of the older worker, the health resort as part of the public health service, the milk supply, the influence of deafness on sickness and disablement benefits, the simplification of national health insurance, and overcrowding in relation to the new Housing Bill. A health exhibition will as usual be attached to the congress, and an attendance of about 1500 members and delegates is expected. Particulars may be had from the secretary of the institute, 19, Buckingham Palace-road, London, S.W.1.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

SOME ASPECTS OF THE PSYCHOLOGY OF KINDNESS

BY MARY ALLEN, M.A. Camb., M.R.C.S. Eng.

KINDNESS, as it is usually understood, is a very extraordinary thing, and has such peculiar and unlooked-for effects on both the giver and the recipient, that it may prove very interesting to investigate it and to learn something more about it. "As it is usually understood" is meant to indicate that there may be another type of kindness not belonging to the instinctual and emotional life, but belonging to the world of the spirit, that which is an ever open door and a true charity. This kindness will be thought of again at the end.

The statement that "It is more blessed to give than to receive," would be upheld by many many people, and it is astonishing to notice how often the receiving of kindness is attended by the spirit of "envy, hatred, and malice and all *uncharitableness.*" "I could not bear you to do it out of kindness. I am only a patient whom you are being decent to." This kind of remark is so often heard from patients, but an even better illustration of what they may feel was demonstrated by one patient in a dream. The patient was a woman, unmarried, aged 32. For reasons into which it is unnecessary to enter, she was having treatment for an extremely small fee. Her dream was as follows:—

> "A very primitive man wearing animal skins had offered her a brooch of great value, and she was searching among her possessions for something to give in return that should be of equal value to the man with the brooch, but not of equal value to her."

On analysis of the dream, the primitive man was found to represent the analyst who had offered her something very valuable for a very small amount of money. Two distinct feelings emerged, one of great admiration and one of distinct contempt. She said that it seemed so foolish and silly to offer her such a valuable brooch for so little, she had not much respect for the man. She gave the impression that she really thought he must be a little weak in the head to have done such a thing. For two interviews before the production of this dream, the analyst had been wondering why there had been such an atmosphere of contempt about, and why the patient had given the impression of being so superior, because at first she had done nothing of the kind.

There is another type of person who laps up kindness like a cat laps up milk, but the more she is given the more she demands, and when the supply fails she turns and rends. Lastly, there is the person who possesses, and is capable of acquiring so little from life, that kindness is an absolute necessity, and is, in some of these cases, thankfully received. It may seem odd to suggest that *in some cases only* the kindness is thankfully received. Is not everyone glad when others are kind to them? Does not everyone like having things given to them? Do not all people thankfully receive? There are indeed comparatively few people who are capable of *taking.* It is far harder to take than to give, it is more blessed to give than to receive.
